Growing by the Masses
Revisiting the Link between Firm Size and Market Power*

Abstract

How are firms’ relative size and market power related? Using merged micro-data about producers and consumers, we show that a firm’s relative size is mainly related to its number of customers, while its market power is associated only with average sales per customer. We study the macroeconomic implications of these facts by developing a firm dynamics model with customer acquisition and endogenous markups. By allowing firms to grow through customer acquisition, our model associates higher concentration at the top of the productivity distribution with a lower aggregate markup. Nonetheless, our quantitative analysis reveals (1) higher markup dispersion relative to conventional models and (2) large welfare and efficiency losses due to misallocation of customers across firms. By concentrating customers among more productive firms, the efficient allocation achieves 10.8% higher aggregate productivity, 14.6% higher output, and 13.6% higher welfare than the equilibrium allocation.

JEL Codes: D61, D24, D43, E22

Key Words: Misallocation, Customer acquisition, Markups, Concentration

1 Introduction

Canonical macroeconomic models of endogenous markups generate a close relationship between relative firm size and market power at the micro level and a similarly tight link between concentration and misallocation at the macro level. While these relationships follow from the assumption that all firms face the same individual demand curve in these models, in reality, firms spend a vast amount of resources on expanding their customer bases, i.e., to shift their demand curves.\(^1\) How does endogenous customer acquisition change our understanding of the relationship between concentration, market power, and misallocation?

In this paper, we answer this question by empirically and theoretically analyzing how each demand margin contributes to firms’ relative size and market power. First, we exploit a merged micro-level dataset between individual product-level consumption data and producer-level data to uncover the role of the intensive and extensive margins of demand for concentration and market power. Our motivational evidence reveals that while firms’ relative sizes are mainly related to their numbers of customers (the extensive margin of demand), their market power is associated only with the average sales per customer (the intensive margin of demand). Second, we develop a theoretical framework with endogenous customer acquisition and variable markups consistent with these facts. The model predicts an equilibrium relationship between relative size and market power and, compared to conventional models, generates different implications for how misallocation, concentration, and market power are related. Third, to study these implications, we quantify efficiency losses from the misallocation of demand across firms. We find that, relative to the efficient allocation, equilibrium aggregate TFP and output are 10.8% and 14% lower, respectively.

Our first contribution is to document three new facts by merging the Nielsen Homescan Panel and Compustat datasets. First, differences in the sizes of firms’ customer bases account for three-quarters of the variation in firms’ sales. Second, firms’ markups are not correlated with the size of firms’ customer bases. Instead, they are positively associated only with their average sales per customer. Third, we find that firms’ non-production expenses are positively associated with the acquisition of new customers but not with the retention of their existing customers, nor with their average sales per customer. These findings are consistent with the view that firms have the ability to shift their demand by expanding their customer bases.

Our empirical findings serve as the foundation of the theory that we develop to understand the relationship between different sources of relative firm size and market power. Our model of firm dynamics incorporates two key ingredients. First, monopolistically competitive firms with heterogeneous productivity spend resources to acquire new customers in the presence of

\(^1\)Arkolakis (2010) reports total spending on marketing of as high as 5% of GDP in the US.
business-stealing externalities. Second, variable markups arise from firms facing semi-kinked demand schedules from their customers as in Kimball (1995), capturing the notion that each customer’s demand for any product is more elastic at a higher relative price (i.e., Marshall’s second law of demand). Hence, while the total number of customers only shifts firms’ demand, as in Phelps and Winter (1970), their demand elasticities are governed by the individual demand curve of each customer. Thus, market power is independent of the size of a firm’s customer base and depends only on its average demand per customer. These mechanisms link the model to our three motivating facts: Our model allows firms to grow through both margins of demand (first fact), creates a comovement between markups and average sales per customer, but not between markups and the number of customers (second fact) and implies an endogenous relationship between sales and non-production costs (third fact).

By allowing firms to grow through the extensive margin of demand, our model breaks the direct relationship between relative firm size and demand elasticity generated by the exogenous shape of the demand curve in the canonical models. Instead, such a relationship arises endogenously as an equilibrium outcome with different counterfactual implications. Since the extensive margin, which is the main contributor to firms’ relative sizes, only shifts demand, it does not directly affect their demand elasticities and markups. However, this channel allows for a relationship between size and market power through the costs and benefits of customer acquisition instead of a direct relationship between demand elasticity and relative size. More productive firms charge higher markups to each customer and thus anticipate higher gains from additional customers. Therefore, higher markup firms also invest more in their customer bases, subject to technological constraints on customer acquisition. Hence, once matched to the data, our model generates a similar relationship between relative firm size and market power, but one that is inherently different from conventional models and has notably different macroeconomic implications.

To study these macroeconomic implications, we characterize the efficient allocation in our model. Under this allocation, the social planner increases aggregate productivity by allocating more customers towards more productive firms while equalizing the relative demand per customer across weakly substitutable varieties. This result contrasts with the efficient allocation in conventional models, where the planner uses the intensive margin of demand to target two mutually exclusive objectives: concentrate demand among more productive firms to increase aggregate productivity versus equalize demand across varieties to eliminate utility losses from demand dispersion. In our model, this trade-off is non-existent because the planner uses both margins of demand as instruments to achieve both objectives.

Even though our model features a margin of demand that is not necessarily associated with market power, welfare losses are potentially large. This result follows from the observation that
the endogenous allocation of customers pushes the Pareto frontier of our economy beyond what models without this extensive margin would suggest. While the uniform allocation of customers across firms is still feasible, the planner improves on this allocation by concentrating customers among more productive firms. Hence, welfare losses could be large if the equilibrium allocation of customers is sufficiently distorted. Thus, our analysis unveils a novel source of efficiency losses due to the misallocation of customers.

Next, we calibrate the model to study its quantitative implications. Most notably, we aim to measure the differences in the allocation of customers, aggregate productivity, and welfare between the equilibrium and the efficient allocation. One of the key challenges in this analysis is to identify model parameters that determine the equilibrium allocation of customers across firms. To do so, we devise a strategy based on the model’s predictions that we implement with available data on firms’ sales and cost structures. At the core of this strategy is the comovement between a firm’s sales and its non-production expenses (conditional on production expenses that control for confounding factors), which is informative of returns to scale in the customer acquisition technology.

With the calibrated model at hand, we conduct two exercises to analyze the consequences of endogenous customer acquisition in a model with variable markups. First, we compare the equilibrium allocation with the one obtained in a version of the model where customers are homogeneously distributed across firms (as in conventional models). By exogenously fixing the size of firms’ customer bases, this model allows firms to grow only through selling more per customer, which has sizable aggregate consequences. To perform comparative statics, we compare the two models under the same parameter values. The top 5% sales share declines from 50% in the baseline model to 17% in the homogenous customers model, but the aggregate markup increases from 26% to 38%. Also, the homogeneous customers model features higher entry but much lower aggregate TFP and output by giving more customers to less productive firms.

How does the model change our understanding of the relationship between relative size and market power? To answer this question, we recalibrate the homogenous customers model to the same set of moments that we use in our baseline calibration (which, notably, includes the relative size distribution). Comparing the two, we find that our model associates a higher degree of markup dispersion with the same moments, which anticipates a higher degree of misallocation.

Our second quantitative exercise is to quantify the degree of misallocation implied by our model. We find that the misallocation of demand has large negative effects on efficiency and welfare: the consumption equivalent welfare gains of the representative household under the efficient allocation is 13.6%. The majority of this gain comes from the efficiency gains in aggregate TFP under the planner’s allocation, quantified at 10.8% higher than in the equilibrium. The
planner achieves higher aggregate TFP by reallocating customers from low-productivity firms to the most productive ones. Indeed, in the efficient allocation, the top 5% sales share increases by almost 40%, and the number of operating firms declines by 11%. Finally, we verify that these results are mainly driven by customer misallocation, which in the equilibrium is determined by the degree of decreasing returns to advertising. To do so, we show that by moving halfway from the calibrated model to an economy with constant returns to advertising, the differences across allocations become much less pronounced. For example, compared to this alternative equilibrium, the efficient allocation generates only 3.2% higher TFP, 4% higher welfare, and 15% higher concentration.

**Literature review** Our paper is closely related to canonical macroeconomic models of endogenous market power, such as Rotemberg and Woodford (1992), Atkeson and Burstein (2008), and Jaimovich and Floetotto (2008), which predict a positive relationship between a firm’s market share and its ability to exert market power. Among more recent work, our paper is related to Burstein, Carvalho, and Grassi (2020) who provide novel evidence on how markups and relative size are related at the firm, industry, and aggregate level, and Edmond, Midrigan, and Xu (2018) who study the cost of markups in a firm dynamics model with Kimball demand. Our contribution to this literature is twofold. From an empirical perspective, we provide evidence that market power is associated only with average sales per customer. From a theoretical perspective, we provide a theory that links market power to the empirically relevant measure of concentration. By endogenizing the extensive margin of demand in our framework, our calibrated model associates market concentration with higher markup dispersion but lower aggregate market power.

Our model also relates to a large body of work that analyzes the consequences of endogenous customer acquisition through marketing or advertising activities (see, e.g., Arkolakis, 2010; Perla, 2019). Moreover, Fitzgerald, Haller, and Yedid-Levi (2016) and Argente, Fitzgerald, Moreira, and Priolo (2021) present empirical and model-based evidence in different settings in favor of these models. In a related theme, Kaplan and Zoch (2020) analyze the implications of expansionary activities of firms for the distribution of labor income. Finally, a recent analysis by Einav, Klenow, and

---

2 A similar relationship holds in models used in the international trade literature (see, e.g., Gopinath and Itskhoki, 2010; Hottman, Redding, and Weinstein, 2016; Amiti, Itskhoki, and Konings, 2019).

3 Thus, our model echoes a familiar argument against using measures of concentration to make predictions about changes in market power. A similar point has been raised by Syverson (2019), Neiman and Vavra (2019) and Covarrubias, Gutiérrez, and Philippon (2020). For empirical analysis of the relationship between concentration and market power, see De Loecker, Eeckhout, and Unger (2020), Crouzet and Eberly (2019) and Autor, Dorn, Katz, Patterson, and Van Reenen (2020).

4 See, also, Drozd and Nosal (2012); Sedláček and Sterk (2017). Furthermore, for models of customer acquisition through dynamic pricing see Phelps and Winter (1970); Bils (1989); Rotemberg and Woodford (1999); Ravn, Schmitt-Grohé, and Uribe (2006); Nakamura and Steinsson (2011); Dinlersoz and Yorukoglu (2012); Gourio and Rudanko (2014); Foster, Haltiwanger, and Syverson (2015); Cabral (2016); Gilchrist, Schoenle, Sim, and Zakrajšek (2017); Hong (2017); Paciello, Pozzi, and Trachter (2018); Bornstein (2021). We further discuss the relationship between our paper and these two branches of the literature in Section 3.7.
Levin, and Murciano-Goroff (2020) provides broader evidence of the importance of the sizes of firms’ customer bases for their relative sizes and studies the implications of customer acquisition in a growth model with constant markups. Relative to this literature, our main empirical contribution is to document the relationship between markups and different margins of demand. Furthermore, our main theoretical contribution is to analyze a model with variable markups and endogenous customer acquisition based on advertising activities. We embed this framework in a firm dynamics model (as in Hopenhayn, 1992) to study the misallocation of demand across firms by providing a comparison between the equilibrium and the efficient allocations.

Our paper is also related to the literature that analyzes the role of misallocation of production inputs across firms in affecting aggregate TFP (see the seminal work by Restuccia and Rogerson, 2008; Hsieh and Klenow, 2009). This literature has focused on multiple sources of misallocation: endogenous market power (Edmond, Midrigan, and Xu, 2018; Peters, 2020), information frictions (David, Hopenhayn, and Venkateswaran, 2016), adjustment costs (Asker, Collard-Wexler, and De Loecker, 2014), financial frictions (Buera, Kaboski, and Shin, 2011; Midrigan and Xu, 2014), and the interaction between frictions and the input-output structure of production (Baqee and Farhi, 2019; Bigio and La’O, 2020). We contribute to this literature by highlighting a new source of distortions in aggregate productivity that stems from the misallocation of customers across firms.

Layout The paper is organized as follows. Section 2 describes the data and conducts the empirical analysis. Section 3 presents the model, and characterizes both the equilibrium and the efficient allocation. Section 4 presents the calibration strategy and results. Section 5 compares the baseline model with a restricted model to illustrate the role of endogenous customer acquisition. Section 6 quantifies efficiency losses. Finally, Section 7 concludes.

2 Motivating Facts

This section documents three new facts using micro-level data that shed light on the importance of customer bases for firm dynamics and price-cost markups. To summarize, we find:

Fact 1. Firms mainly grow by acquiring new customers instead of increasing their average sales per customer.

Fact 2. Price-cost markups are correlated only with average sales per customer and are unrelated to the number of customers.

Fact 3. The acquisition of new customers is associated with the firm's non-production expenses, whereas average sales per customer are not.

See, also, Guillouët (2021) for a similar analysis and results using data from Mexico.
Our theoretical analysis in Section 3 integrates these facts to understand the implications of customer acquisition for misallocation, market concentration, and welfare.

2.1 Data Description

We construct a detailed customer-firm-matched dataset to decompose firms’ sales into the size of their customer bases and average sales per customer. Formally, we consider the following exact decomposition of log sales of firm $i$:

$$\ln S_i = \ln m_i + \ln \left( p_i q_i \right),$$  \hspace{1cm} (2.1)

where $m_i$ is the number of firm $i$’s customers, $p_i$ is its price, and $q_i$ is the average quantity purchased per customer.

To measure the number of each firm’s customers, we use the Nielsen Homescan Panel, made available by the Kilts Marketing Data Center at the University of Chicago Booth School of Business. The data contain approximately 4.5 million barcode-level product sales recorded from an average of 55,000 households per year in the United States. Nielsen samples households and provides in-home scanners so that households can record their purchases of products with barcodes. A barcode is a unique universal product code (UPC) allocated to each product and is used to scan and store its information. Each household is assigned a sample weight—or a projection factor—by Nielsen based on ten demographic variables to make the sample nationally representative.\(^6\) Nielsen assigns a broad product-group label for each product, such as pet food and school supplies, and records information about the retailer a household visited to purchase products at a given time. According to Nielsen, the Homescan Panel covers approximately 30 percent of all household expenditures on goods in the consumer price index (CPI) basket. The data we use covers the 2004-2016 time period.

Next, we incorporate firm-level balance sheet information from Compustat to analyze firms’ cost structures. Compustat includes panel data on publicly traded firms since 1960. With the caveat that this dataset covers only publicly listed firms, it constitutes the main source of data for firm-level analysis in the US and has been used in the recent literature on price-cost markups (see, for example, De Loecker, Eeckhout, and Unger, 2020; Traina, 2019). Throughout the analysis, we focus on two measures of a firm’s costs from Compustat. From an accounting perspective, a firm’s costs associated with the running of the firm are captured in the Operating Expense (OPEX), which is divided into the Cost of Goods Sold (COGS, production costs) and Selling, General, and Administrative Expenses (SGA, non-production costs). According to Compustat, COGS includes “all expenses that are directly related to the cost of merchandise purchased or

\(^6\)The ten demographic variables are: household size, household income, head of household age, race, Hispanic origin, male head education, female head education, head of the household occupation, the presence of children, and Nielsen county size.
the cost of goods manufactured that are withdrawn from finished goods inventory and sold to customers”. It records costs attributable to the production of the goods sold by a firm, and its typical categories are the cost of labor and intermediate inputs used in production. On the other hand, SGA expenses include “all commercial expenses of operation (such as expenses not directly related to product production) incurred in the regular course of business...”. It includes the costs incurred to sell and deliver products and services and the costs to manage the company, and its typical categories are advertising, marketing, shipping, research and development, among others.

Finally, we combine the Nielsen database with GS1 US Data Hub to group individual products according to their producing firms and to merge in other firm-level information from Compustat. GS1 is the business entity that provides barcodes to products and records the firm name for each UPC available in the Nielsen data. The definition of a firm is based on the unit that purchased barcodes from GS1. Therefore, a firm in our data corresponds to either a manufacturer or a retailer. This merge procedure provides a unique link between customer- and producer-level data for each firm.

Table 1 presents summary statistics of the customer-firm matched data. Nielsen-GS1 data reveals that much of the firm-group-year sales are driven by the number of customers, not by average sales per customer: More than 500,000 customers spend only $10 approximately for each product group and firm per year on average. Among the total number of customers firms serve in product group \( g \), approximately half of them are new customers in any given year. Inspecting the SGA-to-OPEX ratio shows that non-production costs represent on average approximately 30% of the total costs and are an important component of a firm’s total operating costs. However, there is a large degree of heterogeneity in firms’ cost structure in the Nielsen-Compustat matched data. For example, the p90-p10 gap of the SGA-to-OPEX ratio is around 50 percentage points. Although we only have 332 firms in the Nielsen-Compustat matched data, these cover close to one-fourth of total sales in Nielsen. Appendix A provides a description of the data-cleaning procedure along with a more detailed description of the data.

2.2 Results

2.2.1 The Role of Customer Base for Sales Growth

We start by documenting that the main source of variation in firm sales is the variation in the number of customers rather than average sales per customer. Following Equation (2.1), Table 2

---

7We match the Nielsen-GS1 database with the Compustat database, similar to what has been done in Argente, Lee, and Moreira (2018). We use the “reclink” STATA software command based on the company name after standardizing it with the “std_compname” command (Wasi and Flaaen 2015). Once Stata reports the matching rate for each observation, we keep those having higher than a 0.99 matching rate. We manually check the company name for every observation and drop inconsistent matches.

Notes: The Nielsen-GS1 data in Panel A has 40,418 firms and 109 product groups in the period of 2004-2016. \(S_{igt}\) denotes sales of firm \(i\) in product group \(g\) and time \(t\), \(p_{igt}q_{igt}\) average sales per customer, \(m_{igt}\) number of customers, \(m^\text{New}_{igt}\) new customers in year \(t\) who did not purchase products in year \(t-1\), and \(m^\text{Old}_{igt}\) customers who purchase the products consecutively in year \(t-1\) and \(t\) (\(m_{igt} = m^\text{New}_{igt} + m^\text{Old}_{igt}\)). \(S_{igt}\) is measured in thousands of US dollars, and \(m_{igt}, m^\text{New}_{igt}, \) and \(m^\text{Old}_{igt}\) are in thousands of customers. All Nielsen variables are projection-factor adjusted. The Nielsen-Compustat matched data in Panel B has 332 firms in the period of 2004-2016. All cost-side variables are in millions of US dollars and are deflated by the GDP deflator.

decomposes the variance of log sales into the variances of log average sales per customer and log number of customers, as well as the covariance between these two components. The number of customers accounts for approximately 80% of the variation in sales across firms. Average sales per customer, on the other hand, accounts for approximately 11% of the variance of sales, with the covariance accounting for the rest. These results parallel the findings in contemporary work by Einav, Klenow, Levin, and Murciano-Goroff (2020). Using transaction-level data for a broad set of industries, they document that differences in customer bases account for 74% of sales variation across merchants. This shows that our finding extends beyond the consumer packaged goods sector and is representative of similar patterns in a wider set of industries.

\footnote{Our decomposition results are similar when we instead use the first-difference of log sales; approximately 78%, 20%, and 2% of the variation are explained by the \(\Delta\) log number of customers, \(\Delta\) log average sales per customer, and the covariance between the two, respectively.}
\[

\]

Table 2: Decomposing the Variance of Sales

Notes: \(S_{igt}\) denotes sales, \(p_{igt}\) average sales per customers, and \(m_{igt}\) the number of customers. We use 557,820 firm-group-year-level observations in Nielsen-GS1 data. Sales and the number of customers are projection-factor adjusted.

In addition to decomposing sales in the cross-section of firms, we find that the acquisition of new customers is also the main driver of firms’ sales growth. As firms enter the economy, they can grow either by selling more per customer or by selling to more customers. To document this fact, we analyze firm growth patterns after entry. We mark a firm’s entry as the time when it appears in our data for the first time. To be conservative, we drop entry events that occurred in the first four years in the dataset.\(^9\) To quantify the importance of each margin, we estimate the following equation:

\[
\ln S_{it} = \sum_{a=1}^{8} \delta_a \mathbf{1}(\text{age}_{it} = a) + \lambda_i + \lambda_t + \varepsilon_{it}, \quad (2.2)
\]

where \(S_{it}\) stands for sales and its components of firm \(i\) in year \(t\), \(\text{age}_{it}\) is the number of years firm \(i\) stayed in the economy after entry in year \(t\), and \(\lambda_i\) and \(\lambda_t\) are the firm and year fixed effects, respectively (see Argente, Lee, and Moreira (2019) for a similar analysis of the life-cycle of individual products). The parameters of interest are \(\delta_a\), which measure the dynamics of average sales and its components over the life-cycle of the firm.

Regardless of the firm age, sales growth is mostly attributed to the increase in the number of customers. Figure 1 plots the log sales as a function of firm age (\(\delta_a\) as a function of \(a\)) and decomposes it into the log number of customers and log average sales per customer. At age 1, differences in the number of customers explain approximately 78\% of differences in sales, whereas average sales per customer explain approximately 22\% of sales. Although the importance of the number of customers decreases as firms become older, on average, it still explains approximately 70\% of sales for the maximum firm age observed in the data. Results are robust to including only those firms that survive at least 3 or 5 consecutive years and analyzing average monthly sales as the dependent variable, which accounts for staggered entry throughout the year. Since the degree of durability of a product might affect the ability of firms to grow through different margins, we repeat the analysis by splitting products according to their durability and find similar patterns within both subsamples. See Appendix B for further details.

\(^9\)There is a large increase in the number of households and firms in the Nielsen Homescan Panel data in the years 2006 and 2007. We drop the years 2004-2007 to make the analysis conservative. Thus, the maximum firm age in our sample of entrants is eight years.
Figure 1: Decomposition of Firm Sales Growth by Firm Age

Notes: This figure plots the average firm sales, sales per customer, and the number of customers for each firm-age based on Equation (2.2), after controlling for firm and year fixed effects. The blue circled line shows the results for log sales, the red diamond line for the log average sales per customer and the green triangle line for the log number of customers. There are 40,442 observations and 9,990 firms that newly enter the economy starting from the year 2008 in the Nielsen-GS1 data. All estimates are normalized based on age 0. All variables are projection-factor adjusted.

2.2.2 The Relationship between Firm Size and Markups

Armed with the empirical evidence showing that differences in firms’ size stem mainly from differences in the size of their customer bases, we revisit the predictions of a large class of models that relate firms’ relative market power to their relative size. These models predict that larger firms charge higher markups. Since in most of these models every firm produces only one product, one can take this prediction to the data either at the firm-level or at the product-level. We do both: We first present results at the firm-level and then provide evidence that these results extend to the product-level.

Evidence Based on Firm-level Markups Our decomposition of firms’ sales in Equation (2.1) raises the following question: which margin of sales captures the relationship between relative size and markups? We answer this question by estimating the following regression equation at the firm level:

$$\ln \text{Markup}_{it} = \alpha_1 \ln p_{it} q_{it} + \alpha_2 \ln m_{it} + \lambda_{s,t} + \epsilon_{it},$$

(2.3)

where Markup$_{it}$ is the price-cost markup charged by firm $i$ at time $t$. The sector-year fixed effects $\lambda_{s,t}$ absorb all the variation at the sector-year level, which allows us to interpret markups and measures of size in relative terms, consistent with the theory. To measure markups, we
follow the methodology by De Loecker, Eeckhout, and Unger (2020), where markups are equal
to the inverse variable cost share of sales multiplied by the output elasticity of those variable
inputs. Because this methodology does not require information on all variable costs, we follow
De Loecker, Eeckhout, and Unger (2020) and use data on COGS from Compustat as a measure
of variable costs. In addition, since we are interested in relative markups within industries at
a given point in time, our specification in Equation (2.3) absorbs the output elasticity with the
sector-year fixed effects.\footnote{The main challenge in the estimation of markups lies in the estimation of the output elasticity using only data on firms’ revenues (see Bond, Hashemi, Kaplan, and Zoch, 2021). Given our focus on relative markups and our log regression specification, we do not need to estimate output elasticities. Instead, our regression specification incorporates a set of fixed effects that absorb these output elasticities. The underlying assumption we make, which is standard in the literature, is that the output elasticity with respect to COGS remains constant across firms within an industry and/or time.}

\caption{Markups, Sales per Customer, and Number of Customers}
\end{table}

Notes: * \( p < 0.10 \), ** \( p < 0.05 \), *** \( p < 0.01 \); standard errors are clustered at the firm-level. Markups are measured as the Sales-to-COGS ratio. The variable ln \( p_{it} q_{it} \) denotes the log of the average sales per customer and ln \( m_{it} \) denotes the log number of customers. SIC industries corresponds to a two-digit SIC code. All Nielsen variables are projection-factor adjusted.

We find that firms’ markups are highly correlated with their average sales per customer but
are unrelated to their number of customers, as reported in Table 3. Results are robust to including
different combinations of year and sector fixed effects, showing that the identified relationships
hold within sectors by year.\footnote{The sector fixed effects allow us to interpret that firms that sell more per customer have higher price markups \textit{within} their sector. The advantage of this firm-level analysis is that it allows us to measure relative markups directly. However, it raises the question of whether this relationship is coming from within-firm products or is due to compositional effects across products. Since this approach measures price markups at the firm level in a limited sample, we cannot include fixed effects for products available in the Nielsen data nor for more disaggregated SIC codes. However, as discussed below, we use two alternative approaches to measure markups at the product (UPC) level and include more disaggregated product fixed effects in Appendix B.3. We find that the reported relationships hold within sectors by year.} With the inclusion of industry-time fixed effects, our results show
that firms that charge higher markups have a higher market share in terms of average sales per customer, but not in terms of the number of customers. Thus, the relevant notion of relative size for markups is based on average sales per customer. Appendix B presents results of an alternative specification that includes both total sales and average sales per customer as regressors. Given the decomposition in Equation (2.1), it is not surprising that markups are only associated with the average sales per customer but not with total sales.

**Evidence Based on Product-level Markups** Our results in Table 3 are limited by the scope of the Compustat dataset, which focuses on large public firms and firm-level markups. To demonstrate the external validity of these results, we perform two complementary analyses by using alternative measures of markups and sales. In the first approach, we measure the retailer-product-level markup as the difference between the retailer-product-level price available from the Nielsen Homescan Panel data and the wholesale cost obtained from the Nielsen PromoData, which is based on Gopinath, Gourinchas, Hsieh, and Li (2011) and Stroebel and Vavra (2019). In the second approach, we analyze the relationship between markups and each margin of demand by exploiting the rich dimensions of the data that allow for controlling for marginal costs through an extensive set of fixed effects. This approach is similar to that of Fitzgerald, Haller, and Yedid-Levi (2016) and is valid under the assumption of common marginal costs across different subsets of observations. Both approaches include product fixed effects which allow for analyzing the relationships within a given product. Appendix B.3 provides detailed descriptions of both approaches.

Although we switch the focus to product-level markups and a broader sample of products and firms, both of these alternative approaches generate results consistent with those in Table 3: Markups are positively associated with average sales per customer, but not with the number of customers.

**2.2.3 Customer Acquisition and Firms’ Non-production Costs**

To what extent do firms control their growth through different sales margins? To investigate this, we use data on SGA expenses, which in part capture firms’ expenditures on expansionary activities, and find that: (1) firms that spend more non-production costs have higher sales, and (2) these costs are associated with the number of new customers firms acquire, but not with the number of customers they retain or average sales per customer.

More specifically, we estimate the following specification:

$$\ln S_{igt} = \gamma \ln \text{SGA}_{it} + X'_{it} \nu + \lambda_{ig} + \lambda_{st} + \lambda_{gt} + \varepsilon_{igt},$$

(2.4)

where $S_{igt}$ stands for sales and its components of firm $i$ in product group $g$ and year $t$, $X'_{it}$ is a vector of firm-time-level control variables, $\lambda_{ig}$ are firm-product-group fixed effects, $\lambda_{st}$ hold within products, supporting the view that they do not arise from compositional effects.
are 2-digit SIC-year fixed effects, and $\lambda_{gt}$ are product-group-year fixed effects. The vector of controls $X_{it}$ includes lagged total sales and lagged total number of customers, which allow us to compare firms with similar relative sizes and customer bases. The coefficient of interest is $\gamma$, which captures the correlation between total sales (and its components) and SGA expenses.

Table 4: Sales and SGA: Decomposition

Notes: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$; standard errors are two-way clustered at the firm and product group level. $S$ denotes total sales, $pq$ the average sales per customers, $m$ the number of customers, $m_{\text{New}}$ the number of new customers, and $m_{\text{Old}}$ the number of old customers. New customers are defined as the customers who do not purchase firm $i$’s products in group $g$ at time $t-1$ but start to purchase those products at time $t$, whereas old customers are the customers who consecutively purchase firm $i$’s products in group $g$ in both $t-1$ and $t$ ($m = m_{\text{New}} + m_{\text{Old}}$). We only use households that consecutively appear in $t-1$ and $t$ in the Nielsen data when we measure $m_{\text{New}}$ and $m_{\text{Old}}$. SIC industries corresponds to a two-digit SIC code. All Nielsen variables are projection-factor adjusted.

As shown in the first column of Table 4, firms that spend more on SGA expenses have larger sales. Moreover, the second and third columns show that approximately 95% ($0.090/0.095$) of the correlation between sales and SGA expenses is due to the correlation between the non-production costs and the number of customers, not to the correlation with the average sales per customer. Finally, the last two columns further decompose the correlation of SGA expenses with the size of firms’ customer bases into the acquisition of new customers and the retention of old customers. To measure these outcomes, we only include households that appear in the Nielsen data in at least two consecutive periods.13 We find that, while there is a strong

---

12 Since the sales in the Nielsen data vary across both a detailed product category in the Nielsen data ("product group") and the major industry code available in Compustat data ("SIC"), we allow for both product-group fixed effects and firm-SIC-code fixed effects to compare products within fine product categories.

13 There is a change in the number of surveyed households every year in the Nielsen data, especially in 2006 and 2007. One concern in using these data is that the entry and exit of customers could arise from entry and exit to the sample. For example, the entry of new customers may not reflect the actual customer acquisition of a firm but may instead reflect an increase in the number of surveyed customers who already purchased this firm’s products. To address this concern, new customers are defined as households that are present in the sample in periods $t-1$ and $t$ but only buy the product at $t$. The exit of customers is similarly defined.
correlation between SGA expenses and the number of new customers, the regression coefficient for old customers is neither economically nor statistically significant. These results show that non-production costs of firms are associated with the acquisition of new customers rather than retaining the existing customer base.\textsuperscript{14} In summary, we have shown that firms’ SGA expenses contribute to relative firm size only through customer acquisition. All facts put together suggest that, by spending on expansionary activities, firms grow through a margin of demand that does not correlate with markups—a distinction not previously studied in the macroeconomics literature.

\textbf{Robustness} In Appendix B.5, we redo the analysis for sub-components of SGA expenses. The results are consistent for the sub-components that are related to expansionary activities (advertising and rent expenses). We find a positive and statistically significant relationship between each of these SGA sub-components and sales, which arises from the customer acquisition margin.\textsuperscript{15}

Anticipating our results in the theory, the extent to which firms can grow through customer acquisition depends on a \textit{variable} component of SGA expenses, which has been a topic of discussion in the recent literature (see Traina, 2019; De Loecker, Eeckhout, and Unger, 2020). The correlation between sales and SGA expenses in Table 4 is indicative of such a variable nature of these costs. However, as we show in Appendix B, this contemporaneous correlation is weaker than the one between sales and COGS—which is commonly considered as a measure of variable production costs. Therefore, total SGA expenses seem to be composed of both variable and fixed components. Although our reduced-form empirical analyses do not allow us to separate these components, in our model we incorporate both components and provide a strategy to measure how much firms can grow through investing in their customer bases.

\section{Model}

Time is discrete and is indexed by $t \in \{0, 1, 2, \ldots \}$. The economy consists of a representative household with a unit measure of individual members denoted by $j \in [0, 1]$ and a measure of firms that operate in a representative industry and produce weakly substitutable goods. We index firms by $i \in N_t$, where $N_t$ is the set and, with a slight abuse of notation, the measure of producing firms at time $t$. We assume that only customers of a firm can purchase its product.

\subsection{Households}

At any given time, the representative household supplies labor to the firms in a competitive labor market and forms demand for the varieties produced by firms, taking their prices as given. We

\textsuperscript{14}As shown in Appendix B, we find similar results in our subsamples of durable and non-durable products.

\textsuperscript{15}On the other hand, other SGA sub-components do not show a statistically significant relationship with sales at the conventional levels, which supports the view that the correlation between sales and SGA expenses is due to firms’ expansionary activities.
let \( m_{i,t} \) denote both the measure and the set of variety \( i \)'s customers, and write \( j \in m_{i,t} \) when member \( j \) is a customer of variety \( i \).

**Preferences** The household members jointly maximize their utility using a Kimball aggregator for aggregating their consumption utility and subject to a standard budget constraint:

\[
\max_{\{C_t, L_t, (C_{i,j,t})_{j \in m_{i,t}}\}} \sum_{t=0}^{\infty} \beta^t \left[ \frac{C_t^{1-\gamma}}{1-\gamma} - \frac{\xi_c}{1+\psi} \right] \\
\text{s.t. } \int_0^{N_i} \int_0^1 1_{\{j \in m_{i,t}\}} \mathcal{Y} \left[ \frac{C_{i,j,t}}{C_t} \right] d j d i = 1 \\
\int_0^{N_i} \int_0^1 p_{i,t} c_{i,j,t} d j d i \leq W t L t + \int_0^{N_i} \Pi_{i,t} d i - T_t, 
\]

where \( c_{i,j,t} \) is the consumption of member \( j \) from variety \( i \), \( p_{i,t} \) is the price of variety \( i \), \( C_t \) is the household’s aggregate consumption, \( L_t \) is total labor supply of the household, \( W_t \) is the wage, \( \Pi_{i,t} \) is the profit of firm \( i \) and \( T_t \) is an aggregate lump-sum tax. Moreover, the function \( \mathcal{Y}(\cdot) \) is strictly increasing and strictly concave with \( \mathcal{Y}(1) = 1 \).

**Demand for Varieties** The first property of the demand is that all the customers of variety \( i \) choose to purchase the same amount, where the other members of the household purchase none of it:

\[
\frac{c_{i,j,t}}{C_t} = \begin{cases} Y^{t-1} \left( \frac{p_{i,t}}{P_t D_t} \right) & j \in m_{i,t} \\ 0 & j \notin m_{i,t}. \end{cases} 
\]

Here, \( D_t \equiv \left[ \int_{i \in N_i} \int_0^1 1_{\{j \in m_{i,t}\}} c_{i,j,t} \mathcal{Y}' \left( \frac{c_{i,j,t}}{C_t} \right) d j d i \right]^{-1} \) is an aggregate demand index and \( P_t \) is the price of the aggregate consumption good, which, henceforth, we normalize to one.\(^{17}\) Therefore, the household’s total demand for variety \( i \) is proportional to the number of its customers and is characterized by the following inverse demand function:

\[
\frac{p_{i,t}}{P_t} \equiv D_t \mathcal{Y}'(q_{i,t}) ,
\]

\(^{16}\)In the case of the CES aggregator, \( \mathcal{Y}(x) = x^{1-\sigma^{-1}} \), where \( \sigma \) is the elasticity of substitution across varieties.\(^{17}\)In the special case where the aggregator is CES, this demand index takes a value of \( 1/(1-\sigma^{-1}) \); however, with the generalized Kimball aggregator this quantity is not necessarily a constant. Moreover, one could characterize the equations that pin down \( P_t \) and \( D_t \) in terms of prices rather than quantities. These equations are:

\[
\int_0^{N_i} m_{i,t} \mathcal{Y} \left[ Y^{t-1} \left( \frac{p_{i,t}}{P_t D_t} \right) \right] d i = 1 \\
\int_0^{N_i} m_{i,t} \frac{p_{i,t}}{P_t} \mathcal{Y}'^{-1} \left( \frac{p_{i,t}}{P_t D_t} \right) d i = 1,
\]

which jointly determine \( P_t \) and \( D_t \).
where \( c_{i,t} \) is total demand for variety \( i \), and \( q_{i,t} \) is the relative demand per customer of variety \( i \). The expression in Equation (3.5) maps our theory of demand to the starting point of our empirical analysis in Equation (2.1), where we decomposed the sales of a firm to its number of customers times its sales per customer. In our model, a similar decomposition holds:

\[
\ln(S_{i,t}) = \ln(m_{i,t}) + \ln(p_{i,t}q_{i,t}) + \ln C_t. \tag{3.7}
\]

It is important to note that this decomposition relies on the homogeneity of household members’ preferences for the variety of firm \( i \), or alternatively on the lack of sorting in how customers are matched to certain firms. In Appendix C, we introduce an extension of the model with heterogeneity in tastes as well as sorting and provide motivational evidence for why we abstract from them.

**Elasticities and Super-elasticities of Demand** To generate variable markups, we use the Kimball aggregator function from Klenow and Willis (2016) for our quantitative analysis:

\[
Y(q) = 1 + (\sigma - 1) e^{\frac{1}{\eta} q^\sigma - 1} \left[ \Gamma\left(\frac{\sigma}{\eta}, \frac{1}{\eta}\right) - \Gamma\left(\frac{\sigma}{\eta}, \frac{q}{\eta}\right) \right], \tag{3.8}
\]

where \( \Gamma(., .) \) is the incomplete Gamma function.\(^{19}\) Intuitively, Kimball demand is a smoothed version of a kinked demand curve (Dotsey and King, 2005; Basu, 2005) such that a customer’s demand is more sensitive to the price when the relative price is higher (i.e., demand satisfies Marshall’s second law of demand). As we show below, this leads to the property that markups are higher when relative prices are lower and demand per customer is higher. Implementing this functional form in Equation (3.6), we can derive the following expression for the relative demand per customer for firm \( i \) at time \( t \):

\[
q_{i,t} = \left[ 1 - \eta \ln \left( \frac{p_{i,t}}{D_t(1 - \sigma^{-1})} \right) \right]^{\frac{\sigma}{\eta}}. \tag{3.9}
\]

Moreover, this specification for \( Y(.) \) is a generalization of the CES case with parameters \( \sigma > 1 \) and \( \eta \geq 0 \) that vary the elasticity and super-elasticity of demand. Formally, these quantities are given by

\[
\epsilon_{i,t} = -\frac{\partial \ln(c_{i,t})}{\partial \ln(p_{i,t})} = \sigma q_{i,t}^{\frac{\sigma}{\eta}}, \quad \epsilon_{i,t}^\prime = -\frac{\partial \ln(\epsilon(q_{i,t}))}{\partial \ln(p_{i,t})} = \eta q_{i,t}^{\frac{\eta}{\sigma}}, \quad (3.10)
\]

where \( \epsilon_{i,t} \) is the expression for the elasticity of demand and shows that with the Kimball aggregator, the demand elasticity is a decreasing function of the relative demand per customer. In the special case when the super-elasticity of demand approaches zero (\( \eta \to 0 \)), we are back to the standard case of the CES aggregator with \( \sigma \) being the constant elasticity of substitution across

---

\(^{18}\)In the empirical analysis, the \( \ln C_t \) term would be absorbed by the industry fixed effects.

\(^{19}\)The incomplete Gamma function is given by \( \Gamma(s, x) \equiv \int_x^\infty t^{s-1} e^{-t} dt \).
varieties.

**Dynamics of Customer Bases** Firms engage in expansionary activities, such as advertising campaigns, to attract new customers from a pool of newly separated consumers. Two processes in the model cause separation and make potential customers available to all firms: at the end of each period, (1) all customers of exiting firms separate, and (2) customers of incumbent firms separate at an exogenous rate of $\delta \in [0, 1]$. Furthermore, we assume that the total number of matches that can be generated in the economy is fixed and exogenous to the advertising choices of firms. Without loss of generality, we normalize the total mass of matches to 1. This implies that while advertising affects the distribution of customers across firms, it does not increase the total number of customers that buy from an industry (see, e.g., Einav, Klenow, Levin, and Murciano-Goroff, 2020, for a similar assumption). We discuss this assumption further in Section 3.7.

Formally, we assume that operating firm $i$ at time $t$ posts $a_{i,t} \geq 0$ ads to acquire new customers. Every available member then draws one ad from the pool of all available ads and is matched to the firm that they draw. Therefore, the number of new customers that firm $i$ acquires at time $t$ is proportional to the number of ads that it posted relative to the total number of ads posted by all firms. Hence, firm $i$’s customer base evolves according to:

$$m_{i,t} \leq (1 - \delta)m_{i,t-1} + \frac{a_{i,t}}{P_{m,t}},$$  

(3.11)

where the inequality captures the notion that there is free disposal of customers should the firm choose to exercise that option. Moreover, $P_{m,t}$ captures the relative nature of advertising and it can be interpreted as the cost of a new customer in units of ads: It is the number of ads that a firm needs to post to get one new customer and is determined in the equilibrium so that the matching market clears ($\int_{i \in N_t} m_{i,t}di = 1$):

$$P_{m,t} = \frac{\int_{i \in N_t} a_{i,t}di}{1 - (1 - \delta)\int_0^{N_t} m_{i,t-1}di}.$$  

(3.12)

This expression shows that the cost of a match decreases with the total number of separated customers and increases with the total number of posted ads by all firms.

**Labor Supply** The household’s labor supply is characterized by the following standard intratemporal Euler equation: $\xi L_t^\psi = W_tC_t^{-\gamma}$.

### 3.2 Firms

On the firm side, we assume a structure with endogenous entry and exit, with the following timeline of events—as summarized in Figure 2. At the beginning of each period, a set of potential entrants are born with an initial productivity and decide whether to enter or not. Incumbents also draw a new productivity in the beginning of each period and decide whether to stay or exit.
After entry and exit decisions are made, all firms pay an overhead cost of operation, decide on advertising campaigns, set prices and produce to meet demand. In the rest of this section, we provide a detailed description of these decisions.

**Entry and Exit Decisions** At each period $t$, a measure $\lambda$ of potential entrants are born, each with an initial productivity $z_{i,t}$ drawn from a log-normal distribution:

$$\ln(z_{i,t}) \sim \mathcal{N}(\bar{z}_{\text{ent}}, \sigma_z^2).$$ (3.13)

We let $\Lambda_t$ denote the set of these potential entrants at $t$. Incumbents, i.e., firms that entered the economy at least one period ago, also draw new productivities according to the following AR(1) process:

$$\ln(z_{i,t}) = \rho \ln(z_{i,t-1}) + \epsilon_{i,t}, \quad \epsilon_{i,t} \sim \mathcal{N}(0, \sigma_z^2)$$ (3.14)

With new productivities drawn, each incumbent or potential entrant then decides whether to stay in the economy or to dropout. We refer to this decision by $1_{i,t} \in \{0, 1\}$, with 1 being an indicator for entering or staying. Finally, all the incumbent firms who decided to stay draw i.i.d. Bernoulli survival shocks, $\nu_{i,t}$, that are equal to 1 with probability $\nu \in [0, 1]$, and drop out if $\nu_{i,t} = 0$.

**Advertising, Pricing and Production Decisions** Firms who stay or enter the economy pay an overhead cost of $\chi > 0$ in units of labor at each period, which allows them to market and produce their product using labor. In particular, firms can use labor to produce ads using the technology $a_{i,t} = l_{i,s,t}^\phi \geq 0$, where $l_{i,s,t}$ denotes the amount of labor allocated to advertising activities. The firm’s customer base then evolves according to the law of motion in Equation (3.11), following Clementi and Palazzo (2016) and Ottonello and Winberry (2020), we allow for the mean of incumbents’ productivity distribution—normalized to 0—to be different than that of entrants, $\bar{z}_{\text{ent}}$. This introduces a natural trend in firms’ productivity based on their age and allows us to account for differences in size across age-groups, as reported in the Business Dynamics Statistics (BDS).
where \( m_{i,t-1} \equiv 0 \) for operating firms that entered at time \( t \). Moreover, \( \phi \in [0,1] \) is the degree of decreasing returns to advertising.

Furthermore, for a given number of customers, a firm's demand is given by Equation (3.5). Firms take this demand schedule as given and choose the price that maximizes their life-time profits. Each firm \( i \) then produces to meet its realized demand using the production function \( y_{i,t} = z_{i,t} l_{i,p,t}^\alpha \), where \( z_{i,t} \) is the firm's productivity, and \( l_{i,p,t} \) is its labor demand for production. Finally, \( \alpha \in [0,1] \) is the degree of decreasing returns to production.

Firms' Problem Given an initial level of productivity and customer base, firm \( i \)'s problem is given by

\[

v_t(m_{i,t-1}, z_{i,t}) \equiv \max_{(q_{i,t}, l_{i,s,t}, l_{i,p,t}, l_{i,s,t})_{t \in \mathbb{N}}} \mathbb{E}_t \sum_{\tau = t}^{\infty} (\beta \nu)^{\tau - t} \left( \prod_{h = t}^{\tau} 1_h \right) \left( \frac{C_T}{C_t} \right)^{-\gamma} \left[ \begin{array}{c} \text{price} \\
\text{total sales} \\
\text{COGS} \\
\text{SGA expenses} \end{array} \right] \\
\left[ \begin{array}{c} D_T \bar{Y}(q_{i,t}) y_{i,t} - W_T l_{i,p,t} - W_T (l_{i,s,t} + \chi) \end{array} \right] \\
\text{subject to} \ \ y_{i,t} = m_{i,t} q_{i,t} C_T = z_{i,t} l_{i,p,t}^\alpha \\
\ m_{i,t} \leq (1 - \delta) m_{i,t-1} + \frac{l_{i,s,t}^\phi}{P_{m,t}}, \ \ l_{i,s,t} \geq 0. 
\]  

The problem states that firm \( i \) maximizes the expected discounted stream of its profits subject to Equation (3.16) that requires firm to meet its demand given its choices of \( q_{i,t} \) and \( m_{i,t} \) and Equation (3.17) that captures the law of motion for the number of firm’s customers and the non-negativity of labor allocated towards advertising. Also, notice that we have separated the terms in the profit function to total sales, COGS, and SGA expenses, all of which we use later to discuss how we map the model to the data.

3.3 Characterization of Firms’ Decisions

In this section, we characterize the firms’ optimal decision rules for pricing, advertising, entry and exit.

Prices and Markups For a firm that has decided to operate in a given period, and for a given choice of advertising that determines its number of customers in that period, the pricing decision has a static nature. Formally, the firm chooses to charge an optimal markup over its marginal cost of production:

\[

p_{i,t} = \frac{\varepsilon_{i,t}}{\varepsilon_{i,t} - 1} \times \alpha^{-1} \frac{W_T l_{i,p,t}}{y_{i,t}}. 
\]  

(3.18)

This expression shows that despite the presence of variable advertising costs, the common proportionality relationship derived in conventional models between the labor share and the markup also holds in our model. This justifies our use of the De Loecker, Eeckhout, and Unger
methodology in identifying markups from the Compustat data.

It is also important to note that the firm’s elasticity of demand, $\varepsilon_{i,t}$, is itself a function of demand per customer in Equation (3.9) and varies with the firm’s pricing choice. Therefore, as long as $\eta$ is not zero, the optimal markup of the firm varies with its marginal cost, which leads to the following lemma.

**Lemma 1.** At a given time $t$, firms with higher marginal costs charge higher prices and lower markups. Formally, let $\mu_{i,t}$ denote a firm’s markup and $mc_{i,t}$ denote its marginal cost. Then, the elasticities of markups and prices to marginal costs are:

\[
\frac{\partial \ln(p_{i,t})}{\partial \ln(mc_{i,t})} = \frac{1}{1 + \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)} \geq 0 \quad (3.19)
\]

\[
\frac{\partial \ln(\mu_{i,t})}{\partial \ln(mc_{i,t})} = -\frac{\eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)}{1 + \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)} \leq 0 \quad (3.20)
\]

*Proof.* See Appendix D.1.

Equation (3.19), which is also known as the *incomplete pass-through* property of Kimball demand (see, e.g., Gopinath and Itskhoki, 2010; Amiti, Itskhoki, and Konings, 2019), shows that for a one percent increase in the marginal cost, the firm’s relative price also increases but by less than one percent. The intuition for this result is that firms with higher marginal costs have to charge higher relative prices to make a positive margin, but since at higher prices demand is more elastic, their optimal markups are lower—in particular, this contrasts with a CES demand system, which requires the elasticity of demand to be constant along the firms’ demand curves.

We are now ready to prove the following proposition that links the model to our empirical fact in Table 3.

**Proposition 2.** At a given time $t$, firms with higher relative sales per customer charge higher markups. Formally,

\[
\frac{d \ln(\mu_{i,t})}{d \ln(p_{i,t}q_{i,t})} \bigg|_{t} = \eta \sigma^{-1} \mu_{i,t}(\mu_{i,t} - 1) \geq 0 \quad (3.21)
\]

*Proof.* See Appendix D.2.

While the relationship outlined by Proposition 2 is independent of firms’ customer bases, the relationship between markups and total sales depends on how firms’ customer bases covary with markups. Definite statements about this relationship require characterizing the optimal advertising strategies of firms; however, the results above are enough to make comparisons across firms with the same relative size:

**Corollary 3.** At a given time $t$, firms with more customers charge lower markups **conditional on**
relative total sales:

$$\frac{d\ln(\mu_{i,t})}{d\ln(m_{i,t})} \bigg|_{\sum_{j \in \mathcal{N}_t} p_{i,j} y_{i,t}} = -\eta \sigma^{-1} \mu_{i,t}(\mu_{i,t} - 1) \leq 0$$  (3.22)

**Proof.** See Appendix D.3.

Corollary 3 follows from the fact that *conditional* on the same relative size within a fixed period, firms with a larger number of customers should be selling less per customer, which by Proposition 2 should charge lower markups. This highlights the main departure of our paper from the literature on variable markups, where customer acquisition is not modeled explicitly, and customers are *homogeneously* distributed across firms. Hence, in conventional models, the fact that a representative consumer buys from all firms and all firms are on the same demand curve implies that relative size (market share) is a sufficient statistic for firms’ markups.

However, in our model, firms can be larger either because they sell more per customer or because they have more customers, and relative size is no longer a sufficient statistic for markups. In fact, Corollary 3 shows that two firms with the same relative size can have different markups, depending on the differences in their number of customers and relative sales per customer. Thus, to study the *unconditional* relationship between relative size and markups, we need to characterize how the number of firms’ customers is related to their sales per customer. This requires the characterization of optimal advertising strategies.

**Advertising Strategies** A key feature of our model is that firms internalize the decision of acquiring customers and can spend resources to do so. For this decision, while the marginal cost of a new customer is determined by the amount of labor that the firm needs to utilize to find it, its benefit is closely linked to the firm’s market power and the amount of additional demand from that customer. The following proposition formulates the optimality condition for firms’ advertising decisions in terms of this cost-benefit analysis.

**Proposition 4.** The optimal advertising strategy of a firm is characterized by

$$\phi^{-1} \left( \frac{W_{i,t} l_{i,t}}{m_{i,t} - (1 - \delta) m_{i,t-1}} \right) = \mathbb{E}_t \sum_{\tau=t}^{\infty} \left( (\nu(1 - \delta))^{\tau-t} \prod_{h=t}^{\tau} 1_{i,h} \right) \times \beta^{\tau-t} \left( \frac{C_{i,t}}{C_{i}} \right)^{-\gamma} (\mu_{i,t} - 1) m_{i,t} q_{i,t} C_{i}.$$  (3.23)

**Proof.** See Appendix D.4.

Equation (3.23) shows that the marginal benefit of acquiring one more customer is linked to the net present value of the gross profits that the firm will earn from that customer for the duration of the match.

It follows from Proposition 2 that the marginal profits generated by a new customer are increasing in the firm’s markups. Therefore, firms that charge higher markups (or expect to charge higher markups on average for the duration of a match) anticipate a higher return on
investing in their customer base. Hence, our model predicts a positive relationship between markups and the size of firms’ customer bases in the equilibrium. This can be more easily seen for the special case with $\delta = 1$, which allows for an analytical solution for the optimal customer base $m_{i,t}$ as a function of static profits per customer:

$$m_{i,t} = \frac{[(1 - \mu_i^{-1}) p_{i,t} q_{i,t}]^{\frac{1}{\phi - 1}}}{\int_{i \in N_t} [(1 - \mu_i^{-1}) p_{i,t} q_{i,t}]^{\frac{1}{\phi - 1}} d i},$$

(3.24)

where the numerator is increasing in the firm's markup by Proposition 2.

**Entry and Exit Policies** A potential entrant enters the economy and an incumbent decides to stay if their value, specified in Equation (3.15), is positive: $v_t(m_{i,t-1}, z_{i,t}) > 0$. It can be shown that firms’ value functions are increasing in their productivity and hence, for any given level of $m_{-1}$, there is a threshold productivity $z^*(m_{-1})$ such that firms with productivity higher than $z^*(m_{-1})$ stay or enter the economy (see Hopenhayn, 1992).

### 3.4 Equilibrium

A monopolistically competitive equilibrium for this economy is: (a) an allocation for the households $\{c_{i,j,t} \in [0,1], C_t, L_t\}_{t \geq 0}$, (b) a set of exit decisions for potential entrants and incumbents $\{(1_{i,t})_{i \in \Lambda_t \cup N_{t-1}}\}_{t \geq 0}$, (c) an allocation for operating firms $\{(p_{i,t}, y_{i,t}, m_{i,t}, l_{i,p,t}, l_{i,s,t})_{i \in N_t}\}_{t \geq 0}$, (d) a sequence of aggregate prices $\{W_t, P_{m,t}\}_{t \geq 0}$ and a sequence of sets $\{N_t\}_{t \geq 0}$; such that,

1. given (c) and (d), households' allocation in (a) solves their problem in Equation (3.1),
2. given (a) and (d), firms’ allocations in (b) and (c) solve their problems in Equation (3.15),
3. labor and matching markets clear: $L_t = \int_{i \in N_t} (l_{i,p,t} + l_{i,s,t} + \chi) d i$, 1 = $\int_{i \in N_t} m_{i,t} d i$,
4. the set of operating firms, $N_t$, evolves according to

$$N_t = \{ i \in \Lambda_t \cup N_{t-1} : 1_{i,t} v_{i,t} = 1 \}, N_{-1} \text{ given.}$$

(3.25)

**Solution Method** We solve the model globally by combining collocation methods and non-stochastic simulation to approximate the distribution of firms over $(z_{i,t}, m_{i,t-1})$. Appendix E provides a description of the recursive formulation of the firm's problem and the computational algorithm that finds the steady state of this economy.

### 3.5 Aggregation

Given a set of operating firms, $N_t$, along with an allocation of production inputs and demand $(l_{i,p,t}, m_{i,t}, q_{i,t})_{i \in N_t}$ across these firms, we can recast the characterization of the aggregate output and production labor of this economy in the form of an *aggregated production function* as well as an *aggregate markup*. In the rest of this section, we derive these aggregate objects. We then derive decomposition results, based on these aggregate objects, that will facilitate the comparison of the equilibrium allocation to other counterfactuals, such as the efficient allocation.
**Aggregate Production Function** We start by deriving the aggregate production function, which can be obtained by defining the *total production labor* as the aggregate amount of labor allocated towards production:

\[
L_{p,t} \equiv \int_{i \in N_t} l_{i,p,t} \, di = \int_{i \in N_t} \left( \frac{C_{t} m_{i,t} q_{i,t}}{z_{i,t}} \right)^{\alpha - 1} \, di,
\]

(3.26)

where the second equality follows from equating firms’ demand to their supply.

Defining aggregate output as the aggregate consumption, \( Y_t \equiv C_t \), and rearranging Equation (3.26), we arrive at the aggregate production function:

\[
Y_t = Z_t L_{p,t}^\alpha,
\]

(3.27)

where \( Z_t \), the aggregate TFP, is given by

\[
Z_t \equiv \left[ \int_{i \in N_t} \left( \frac{z_{i,t}}{q_{i,t} m_{i,t}} \right)^{-\alpha - 1} \, di \right]^{-\alpha}.
\]

(3.28)

Notice how the allocation of relative demand \((q_{i,t}, m_{i,t})_{i \in N_t}\) affects aggregate productivity. Higher relative demand means higher production relative to other firms, which decreases aggregate productivity through lower marginal product of labor (due to decreasing return to scale) and dispersion in demand per customer (due to imperfect substitutability of goods).

**Aggregate Markup** Given an allocation of production inputs and prices among a set of operating firms, \((l_{i,p,t}, p_{i,t})_{i \in N_t}\), we define the aggregate markup, \( \mathcal{M}_t \), as the wedge between the aggregate marginal product of labor and the wage \( W_t \). Formally, having derived the aggregate production function in Equation (3.27), the aggregate markup is defined as

\[
\mathcal{M}_t \equiv \frac{\partial Y_t}{\partial L_{p,t}} \frac{W_t}{Y_t} = \alpha Y_t W_t L_{p,t}.
\]

(3.29)

We can also define the firm level markup as the analog of this wedge for firm \( i \):

\[
\mu_{i,t} \equiv \alpha \frac{p_{i,t} Y_{i,t}}{W_t l_{i,p,t}},
\]

(3.30)

which corresponds to the equilibrium relationship between the markup and the labor share in Equation (3.18)—with the exception that here we are defining this wedge for an arbitrary allocation of inputs and prices. By combining the last two equations, we can then derive the aggregate markup as the production cost-weighted average of firm level markups (as in Edmond, Midrigan, and Xu, 2018):

\[
\mathcal{M}_t = \int_{i \in N_t} \omega_{i,t} \mu_{i,t} \, di,
\]

(3.31)
where the weight $\omega_{i,t}$ is the production cost share of firm $i$ or, as referred to by Baqee and Farhi (2019), the cost-based Domar weight of firm $i$:

$$\omega_{i,t} = \frac{W_t l_{i,p,t}}{\int_{i \in N_t} W_t l_{i,p,t}}. \quad (3.32)$$

**Decomposition of Welfare** How does the household's utility change for small deviations around the equilibrium allocation? The following proposition shows that, up to first order, the household's welfare changes only through aggregate objects.

**Proposition 5.** For small perturbations around the equilibrium allocation, changes in household's welfare at a given time $t$ are given, up to a first order approximation, by

$$\frac{\Delta U_t}{U_{C,t,C_t}} \approx \frac{\Delta \ln(Z_t)}{\Delta \text{TFP}} + \alpha (1 - \mathcal{M}_t^{-1}) \frac{\Delta \ln(L_{p,t})}{\Delta \text{from Aggregate Markup}} - \frac{\alpha M_t^{-1}}{L_{p,t}} \left[ \frac{\Delta \ln(N_t)}{\Delta \text{from Entry/Exit}} + \frac{\Delta \ln(L_{s,t})}{\Delta \text{from Advertising}} \right], \quad (3.33)$$

where $Z_t$ is the aggregate TFP in Equation (3.28), $\mathcal{M}_t$ is the equilibrium aggregate (cost-weighted) markup in Equation (3.31), $L_{p,t}$ and $L_{s,t}$ are the aggregate amounts of labor allocated towards production and advertising, and $N_t$ is the equilibrium measure of operating firms.

**Proof.** See Appendix D.5.

Equation (3.33) decomposes the consumption-equivalent welfare changes of the household around the equilibrium allocation to four separate terms: (1) allocative and distributional changes that lead to changes in aggregate TFP, (2) losses due to underutilization of labor in the equilibrium that arise from aggregate market power—and demonstrates itself as a wedge between the marginal product of labor and the marginal rate of substitution between consumption and leisure, (3) changes in aggregate labor supply that is allocated towards the overhead costs of operating firms, and (4) changes in aggregate labor supply that is allocated towards advertising in the equilibrium.

Proposition 5 lays out the road map for the rest of our analysis. As we move on to the quantitative part of this study, our main objective is to measure these welfare changes under counterfactual allocations of demand. In particular, we are interested in the comparison with the efficient allocation of demand and the allocation that arises without the extensive margin of demand.

### 3.6 Efficient Allocation and The Social Planner’s Problem

The endogenous extensive margin of demand creates a new channel for the relationship between relative size and markups. Not only this new channel affects this relationship in the equilibrium, but it also defines a new Pareto frontier for the economy because the social planner now chooses...
the distribution of customers across firms. This section characterizes this efficient allocation in our economy.

Given an initial distribution of firms, the social planner of this economy maximizes the household's lifetime utility by choosing: (1) which incumbent firms should exit and which potential entrants should enter at each period, (2) how many customers each operating firm should get—which can be achieved either by depreciating their customer base if the firm has too many customers or by launching advertising campaigns if the firm needs to grow—and, finally, (3) how much each operating firm should produce. A formal statement of the planner's problem is included in Appendix D.6. Here, we discuss the key properties of the solution to this problem.

**Any Distribution of Customers is Attainable** There are two sources of inefficiencies regarding customer acquisition and the allocation of customers in the equilibrium. First, the planner might choose to allocate customers differently across firms than the equilibrium (misallocation of customers). A second source of inefficiency is the business-stealing externality of advertisement, which leads to an overuse of labor for advertising in the equilibrium. The main objective of this model is to study the misallocation of customers. Therefore, we abstract away from this second source of inefficiency by restricting the social planner to spend the same amount of aggregate labor for advertisement as in the equilibrium. As a result, our estimates of inefficiencies in the equilibrium will only reflect the misallocation of customers across firms.21

Before continuing with the analysis, we next show that shutting down the second source of inefficiencies is inconsequential for the implications of customer misallocation. The following Lemma shows that by restricting the planner to use a certain amount of aggregate labor for advertisement, we are not imposing any restriction on the planner's choices regarding the allocation of customers across firms.

**Lemma 6.** Any desired distribution of customers across a set of operating firms can be achieved by any strictly positive level of aggregate labor allocated towards advertisement.

**Proof.** See Appendix D.7.

This result follows from the advertisement technology, which requires that returns to advertisement are fully relative in labor allocated towards posting ads.

Given this result, we solve the planner's problem in two steps. First, for any set of operating firms, we characterize the optimal allocation of demand in terms of how many customers each operating firm should get and how much they should produce. Second, we characterize the optimal entry and exit rule that determines the sets of operating firms over time.

---

21While this restriction is a choice on our part and could be easily relaxed, it constitutes a clean benchmark that allows us to focus on quantifying the main channel of interest in our analysis, the misallocation of demand across firms.
Optimal Allocation of Demand Maximizes Aggregate TFP

Here, we characterize the efficient allocation of demand for a given set of operating firms. Formally, by an allocation of demand, we mean the choice of (a) allocating customers across firms in \( N_t \)—i.e., \( 1_{j \in m_{i,t}}, \forall j, \forall i \in N_t \) and (b) choosing the relative demand of every matched customer, \( q_{i,j,t}, \forall j \in m_{i,t}, \forall i \in N_t \). Naturally, any allocation of demand must:

1. be consistent with the Kimball aggregator:
   \[
   \int_{i \in N_t} \int_0^1 1_{j \in m_{i,t}} \Upsilon(q_{i,j,t}) d j d i = 1, \tag{3.34}
   \]

2. respect the constraint for the total number of matches:
   \[
   \int_{i \in N_t} \int_0^1 1_{j \in m_{i,t}} d j d i \leq 1. \tag{3.35}
   \]

**Proposition 7.** Fix a choice for the set of operating firms, \( N_t \). Then, the efficient allocation of demand is the one that maximizes aggregate TFP subject to constraints in Equations (3.34) and (3.35). This allocation equalizes demand per matched customer across all firms, and matches more customers to more productive firms:

\[
q_{i,j,t} = 1, \forall j \in m^*_{i,t}, \quad m^*_{i,t} = \frac{z_{i,t}^{1-a}}{\int_{i \in N_t} z_{i,t}^{1-a} d i}. \tag{3.36}
\]

**Proof.** See Appendix D.8.

Proposition 7 shows that the planner equalizes the level of consumption per customer across all firms. Furthermore, to capitalize on the higher efficiency of more productive firms, the planner gives them more customers. This is in contrast to the equilibrium, in which more productive firms have both higher sales per customer and more customers than other firms (but potentially fewer customers than what is efficient).

Our result in Proposition 7 is also at odds with the trade-off that the social planner faces in models where all firms are assumed to serve the representative consumer. On the one hand, the social planner would like more productive firms to produce more to increase aggregate consumption (i.e., to equalize marginal product of inputs across firms). On the other hand, since demand comes from the intensive margin in those models, instructing more productive firms to produce more creates dispersion in relative consumption across varieties, which is costly due...
to the weak substitutability of goods. Therefore, the social planner has to balance these two opposing forces when choosing the optimal allocation of inputs.

However, in our model, the social planner does not face such a trade-off due to the existence of the extensive margin of demand. The optimal allocation equalizes relative consumption across all customers and, instead, equalizes the marginal product of inputs across firms by giving more customers to more productive firms.

More generally, endogenizing the allocation of customers has two important macroeconomic implications. First, it widens the Pareto frontier of the economy because, in our model, the social planner always has the option to replicate the homogeneous allocation of customers across firms. Second, both the magnitude of losses from misallocation and the distance of the equilibrium allocation from this new frontier depend on how effective the equilibrium advertising technology is in replicating the efficient allocation of customers, rather than the efficient allocation of sales per customer, as is the case in the conventional models.

**Social Value of a Firm** In order to compare how the social planner values individual firms relative to the equilibrium, here we characterize the social value of firms under the efficient allocation.

**Proposition 8.** Let $v^*_i(z_{i,t})$ denote the social value of a firm with productivity $z_{i,t}$ at time $t$. Then, this value is given by

$$v^*_i(z_{i,t}) = \max_{\{\mathbf{1}_{i,t}, m_{i,t}^*, q_{i,t}^*, l_{i,t}^*, p_{i,t}^*\}_{t \geq t}} \mathbb{E}_t \sum_{\tau = t}^{\infty} (\beta \nu)^{\tau - t} \left( C_t^* \right)^{-\tau} \left( D_t^* \frac{Y(q_{i,t})}{q_{i,t}} y_{i,t} - W_t^*(l_{i,p,t} + \chi) - C_t^*(D_t^* - 1)m_{i,t} \right)$$

\[ \text{s.t. } y_{i,t} = m_{i,t}^* q_{i,t}^* C_t^* = z_{i,t} l_{i,p,t}^a \]

where $(C_t^*, D_t^*, W_t^*)_{t \geq t}$ are the aggregate consumption, aggregate demand index and the decentralized wage under the planner’s allocation.

**Proof.** See Appendix D.9.

This expression clarifies how the planner’s allocation for a given firm differs from its equilibrium counterpart in Equation (3.15). There are three notable differences. First, the social planner maximizes a firm’s value based on the average consumer surplus ($Y(q)/q$) whereas in the equilibrium the revenue that firms receive is based on the marginal valuation ($Y'(q)$). Second, the advertisement labor cost of allocating customers does not appear in this value because aggregate advertisement labor is a sunk cost for the planner and, at the margin of keeping a firm, it does not affect her decision. Third, there is a new term $(C_t^* (D_t^* - 1)m_{i,t})$ that captures the externalities of allocating customers across firms, which is endogenous to the planner but neglected by individual firms. This externality arises from the fact that there is a fixed pool of customers in the economy, and if one firm is being matched to a particular customer, then
another firm must lose one.

3.7 Discussion of Assumptions

Before moving on to our quantitative analysis, here we discuss our main model assumptions.

Mechanisms for Customer Acquisition In Equation (3.11), we have assumed a law of motion for customers that rules out (1) customer acquisition through prices, and (2) customer retention through firm decisions (i.e., an endogenous separation rate).

The assumption that firms cannot attract new customers by lowering their prices is motivated by our empirical results in Table 3 that markups are not correlated with the size of firms’ customer bases conditional on sales per customer. Fitzgerald, Haller, and Yedid-Levi (2016) also conclude that firms do not manipulate prices to shift demand by documenting that after firms enter into a new market their markups remain the same while their quantities grow. Instead, based on our findings in Table 4, we model customer acquisition through advertising-like activities (as in, e.g., Arkolakis, 2010; Drozd and Nosal, 2012; Sedláček and Sterk, 2017). Table 4 also shows that SGA expenses do not covary with the retention of old customers, which is why we assume that the separation rate of customers is exogenous to firm decisions.

Therefore, in our model, customer acquisition can have the interpretation of a process through which potential customers become “aware” of a product or a firm (as in Perla, 2019). Once they are aware of the product, however, the price affects their demand only in the intensive margin, and it does not affect their decision to leave the firm.

The Relative Nature of Advertising We have made the assumption that advertising, while affecting the distribution of customers across firms, does not increase the total number of customers that buy from an industry—i.e., it has a business-stealing nature (as in Drozd and Nosal, 2012; Einav, Klenow, Levin, and Murciano-Goroff, 2020).\(^\text{23}\) This assumption is supported by evidence from the marketing and IO literature.\(^\text{24}\) For instance, studying the publishing sector, Garthwaite (2014) writes, “[book] endorsements are found to be a business-stealing form of advertising that raises title level sales without expanding the market size.” Similarly, for prescription drugs, Sinkinson and Starc (2019) find a positive own-elasticity of revenue to advertising, but a negative and similar in size negative elasticity of revenue with respect to rival advertising. For consumer packaged goods, Hartmann and Klapper (2018) find that advertising increases revenue per household, but when two major brands advertise together, this revenue is lost. More specifically, in our model, this assumption ensures that independent of how much firms spend on advertising

\(^{23}\)Note that the relative nature of advertising does not affect the estimation of the model, as the stock of customers can always be normalized in the calibration exercise. However, this assumption matters for counterfactual exercises.\(^{24}\)See Bagwell (2007) for a discussion.
within an industry, they cannot increase the total number of customers.\footnote{It is also important to note that in our characterization of the efficient allocation, even the planner is subject to this restriction: she cannot create more customers. This ensures that our measurement of welfare gains does not hinge on more relaxed feasibility constraints for the planner and only comes from reallocation of customers.}

4 Quantitative Analysis

To quantify the implications of customer allocation with variable markups, we calibrate the steady-state of the model using the Simulated Method of Moments and matching several micro and macro moments related to firm dynamics in the US economy in 2012.

4.1 Calibration Strategy

To provide an overview of our calibration strategy, the new and most relevant parameter to calibrate is $\phi$, the returns to scale in advertising—which influences the relationship between a firm's relative size and market power by determining the size of its customer base.\footnote{Note that our model does not require firms to spend on customer acquisition and grow through the extensive margin of demand, and nests the conventional model with exogenous customer bases as a special case. When $\phi \to 0$, every firm receives the same flow of customers in each period, without having to spend on $l_{i,s,t}$. If, in addition, $\delta = 1$, then all firms have the same stock of customers in every period.} As we discuss below, this parameter is identified by the relationship between sales and firms’ expansionary activities included within the SGA expenses. The fact that the latter is only available from Compustat poses a challenge because it contains only a subset of the firms in the economy. We address this challenge in the following way. Whenever possible, we calibrate the model to the aggregate US economy in 2012 by matching moments from the Business Dynamics Statistics (BDS) and Statistics of US Businesses (SUSB) provided by the Census Bureau. When matching moments regarding firms’ costs, we apply a filter in the simulated data to account for the selection into Compustat based on size and age. In the remainder of this section, we provide a detailed description of our calibration strategy.

Fixed Parameters We set the length of a period to one year. Panel A of Table 5 presents the set of parameters that are externally fixed. We set the subjective discount factor $\beta$ to 0.96. The elasticity of intertemporal substitution $\gamma$ is set to 2. We set the inverse of the Frisch elasticity of labor supply to $\psi = 1$ and the labor coefficient in the production function to $\alpha = 0.64$. In the calibration exercise, we normalize the measure of potential entrants $\lambda$ and the disutility of labor supply $\xi$ to generate a steady-state output of $Y = 1$ and wage of $W = 1$.

We set the retention rate of customers to $1 - \delta = 0.72$, which corresponds to the repurchase probability of customers in the Nielsen-GS1 matched dataset in 2012.\footnote{More specifically, define $\text{Sales}_{i,g,t}$ as the total expenditure of (projection-factor adjusted) households who purchase products made by firm $i$ in group $g$ at time $t$. Define the probability of repurchasing firm’s products as $s_{i,g,t} = \frac{\text{Sales}_{i,g,t-1,t}}{\text{Sales}_{i,g,t-1}}$, where $\text{Sales}_{i,g,t-1,t}$ is the total expenditure of (projection-factor adjusted) households who}
GS1 matched data, which is limited to the consumer packaged goods sector, the repurchasing probability is similar in other industries based on evidence from the marketing literature.\textsuperscript{28}

**Calibrated Parameters** We jointly calibrate the remaining 8 parameters by the simulated method of moments (SMM).\textsuperscript{29} These parameters can be grouped in three sets, those shaping firms’ cost structure ($\phi$ and $\chi$), their demand ($\sigma$, and $\eta$), and their life cycle and shock structure ($\rho_z, \sigma_z, \bar{z}_{ent}$ and $\nu$). Although these parameters are jointly identified by all moments, we provide below a discussion of which moment should intuitively be more relevant to identify each parameter. We formalize this discussion in Appendix F by analyzing the local elasticities of model moments with respect to each parameter and the sensitivity measure developed by Andrews, Gentzkow, and Shapiro (2017).

To calibrate the overhead cost $\chi$, we target the cross-sectional average COGS-to-OPEX ratio. The model counterpart of this ratio for firm $i$ is

$$\frac{W_t l_{i,p,t}}{W_t l_{i,p,t} + W_t (l_{i,s,t} + \chi)} = \frac{\text{COGS}_{i,t}}{\text{COGS}_{i,t} + \text{SGA}_{i,t}}.$$  

Intuitively, a larger fixed cost $\chi$, ceteris paribus, should increase a firm’s total costs and drive down this ratio. To measure this ratio, we use data from Compustat. In the model, we compute the moments related to firms’ cost structures after accounting for selection into Compustat with two filters based on firms’ age and size. That is, to compute these moments, we restrict the simulated sample of firms to those that are at least 7 years old, as in Ottonello and Winberry (2020), and have sales above 19% of the average sales in the simulated economy (which corresponds to the ratio of the 5th percentile of the sales distribution in Compustat to average sales in SUSB).\textsuperscript{30}

To identify the elasticity $\phi$, we exploit the observed relationship between SGA and sales in Compustat. The following proposition illustrates the source of identification in the special case of the model with $\delta = 1$, which admits a closed-form solution of the firm’s optimal spending in customer acquisition.

\textsuperscript{28}For example, the repurchase probability is 0.7 in the automotive industry based on survey data used in Mittal and Kamakura (2001). According to Bolton, Kannan, and Bramlett (2000), the loyalty program member share is 0.693 and the cancellation probability is 0.187 for the financial service industry. Finally, Bornstein (2021) estimates an annual retention probability of 0.85 for the top two largest firms in each product category from the Nielsen data. If we also restrict the sample to the top two firms, our retention measure increases to 0.84.

\textsuperscript{29}More specifically, we calibrate the model by choosing a set of parameters $\mathcal{P}$ that minimizes the SMM objective function

$$\left( \frac{m_m(\mathcal{P})}{m_d} - 1 \right)' W \left( \frac{m_m(\mathcal{P})}{m_d} - 1 \right),$$

where $m_m$ and $m_d$ are a vector of model simulated moments and data moments, respectively, and $W$ is a diagonal matrix. Appendix E.2 provides the computational details of the calibration exercise.

\textsuperscript{30}Average firm sales in the 2012 US economy were USD5.7 million (SUSB) and the 5th percentile of the sales distribution in Compustat was USD1.06 million.
Proposition 9. Suppose $\delta = 1$. Then, the total $SGA_{i,t}$ expenses of a firm can be decomposed into a fixed ($SGAF_{i,t}$) and a variable ($SGAV_{i,t}$) component:

$$SGA_{i,t} = SGAF_{i,t} + SGAV_{i,t}$$

$$= W_t \chi + \phi Sales_{i,t} - \frac{\phi}{\alpha} COGS_{i,t}$$

Proof. See Appendix D.10.

Equation (4.1) is obtained from the firm’s optimality condition regarding customer acquisition. As discussed in the model section, firms’ expenditures on customer acquisition are increasing in their markups because they directly determine the returns from customer acquisition. Since $\phi$ is the returns to scale in acquiring new customers, it naturally follows that it should be identified from the sensitivity of SGA expenditures to firms’ markups, which in the model are proportional to firms’ Sales-to-COGS ratio. Thus, intuitively, one can identify the sensitivity of SGA expenses to markups by regressing SGA expenses of firms on their sales while controlling for COGS and time fixed effects (which capture the fixed components of SGA expenses). Proposition 9 formalizes this intuition and show that in the special case of $\delta = 1$, $\phi$ is fully identified by such a regression. The intuition also carries on for the more general case with $\delta < 1$: Appendix F shows a high sensitivity of $\phi$ to the same relationship. Thus, we calibrate $\phi$ to match the coefficient on $Sales_{i,t}$ from an OLS regression of Equation (4.1) using data from Compustat. In the model, we run a similar regression in the simulated data, after applying the same selection to Compustat filters described above.

To calibrate the parameters shaping firms’ demand, we set the elasticity of substitution $\sigma$ to match a COGS-weighted average markup of 1.25 computed from Compustat. This follows from the aggregation result that shows that the relevant aggregate markup corresponds to the production cost-weighted average markup. While the level of markups identifies $\sigma$, the sensitivity of markups to relative size identifies $\eta$. Since we do not directly observe markups, following Edmond, Midrigan, and Xu (2018), we pin down the super-elasticity of demand $\eta$ by the relationship between a firm’s relative average revenue productivity of labor and its relative sales. In a model without customer acquisition, the revenue productivity of labor $p_{i,t}y_{i,t}/W_t l_{i,p,t}$ is directly proportional to the production markup $\mu_{i,t}$, which validates this approach. The following proposition shows that a similar relationship holds in a special case of the model.\(^{31}\) Appendix F shows that the super-elasticity $\eta$ is sensitive to this relationship in the general model as well.

Proposition 10. Suppose $\delta = 1$. Then, a firm’s average revenue productivity of labor is given by

$$\frac{p_{i,t}y_{i,t}}{W_t(l_{i,p,t} + l_{i,s,t})} = \frac{\mu_{i,t}}{\alpha + \phi(\mu_{i,t} - 1)}$$

\(^{31}\)The inverse of this relationship—a firm’s labor share—is the inverse-markup-weighted average of the returns to scale in different uses of labor. A similar relationship appears in Kaplan and Zoch (2020).
which is strictly increasing in the production markup $\mu_{i,t}$ if and only if $\alpha > \phi$.

Proof. See Appendix D.11.

When $\eta = 0$, markups and the revenue productivity of labor are constant and independent of sales. However, markups and the revenue productivity become positively correlated with sales when $\eta > 0$ because demand elasticity decreases with size in proportion to $\eta$. Therefore, the strength of the relationship between labor productivity and sales is informative about $\eta$, holding the other parameters fixed. We summarize this relationship with the regression coefficient of a sales-weighted OLS regression of relative revenue productivity of labor on relative sales of 0.036 for firms with relative sales greater than 1, as reported by Edmond, Midrigan, and Xu (2018) and computed using aggregate data from SUSB.$^{32}$

Finally, the parameters of the AR(1) productivity process for incumbent firms, $\sigma_z$ and $\rho_z$, are set to match a standard deviation of annual employment growth of 0.415 from Elsby and Michaels (2013) and the unweighted distribution of within-industry relative sales from Edmond, Midrigan, and Xu (2018). The mean of the productivity distribution of entrants $z_{ent}$ is set to match the fact that old firms (those older than 11 years) are on average six times larger in terms of employment than 1-year old firms (BDS). The exogenous separation probability $\nu$ is calibrated to match an average exit rate of 7.3% (BDS).

**Calibration Results** The set of calibrated parameters is shown in Panel B of Table 5. The process for the productivity shock is quite persistent and volatile, although in line with estimates from Lee and Mukoyama (2015). The calibrated elasticity and super-elasticity of demand are 6.49 and 4.95, respectively. The value for the elasticity is standard and the value for the super-elasticity is close to estimates found in the literature (see Nakamura and Zerom, 2010); we further discuss how this value compares to calibrated values in the literature in Section 5.2. Finally, note that the calibrated value for the elasticity of the matching function $\phi = 0.533$ is close to a model-generated regression coefficient of 0.474. This similarity lends support to the identification argument provided in Proposition 9.

Table 6 and Figure 3 show the targeted moments and their model counterparts. Overall, the model closely matches the targets. The model reproduces the average cost structure very well, but it slightly under-predicts the relationship between SGA and sales. The model matches

---

$^{32}$In our definition of model revenue productivity of labor, we include the variable component of SGA ($l_v$) but not the fixed component of SGA ($\chi$). The former is due to the fact that the SUSB reports information on the total wage bill across firms in a size group, without distinguishing between types of labor (e.g., production and advertising labor). The decision not to include $\chi$ is due to the fact that part of overhead costs are, in reality, not associated with labor costs (e.g., rent) and thus not included in the wage bill reported by SUSB. Ideally, we would use data on the subcomponents of SGA expenses in Compustat to compute the share of labor costs within SGA expenses. Unfortunately, a full disaggregation of SGA expenses is not available. To alleviate concerns about this choice, note that we target a moment based on a sample of relatively large firms (those with relative sales greater than 1), for which arguably the fixed overhead cost represents a smaller fraction of total costs.

the cost-weighted average markup well and generates a similar relationship between revenue productivity of labor and sales. Figure 3 shows that the model approximates the sales distribution of firms accurately. For example, in the data 33% of firms have sales that are lower than 10% of the average sales in the economy, and 1% of firms have sales that are larger than 10 times the average sales. In the model, these shares are 25% and 1.5%. Figure 3 also shows that the model is able to replicate the relative size of old firms, 6.07 in the data and 6.4 in the model. In Appendix F, we show the untargeted data and model relationships between average labor productivity and SGA with sales, and the average COGS-to-OPEX ratio by firm age and size. Although we targeted specific moments that summarize these relationships in the calibration exercise, the model matches the data patterns more broadly.

### 4.2 Model Validation

Before proceeding with the main quantitative analysis, we provide over-identifying tests of the calibrated model regarding its ability to match relevant untargeted moments. First, we show that

Notes: This table shows the set of moments targeted in the calibration of the model. Slope SGA on Sales refers to the OLS coefficient of the regression $SGA_{i,t} = c + \beta Sales_{i,t} + \psi COGS_{i,t} + \epsilon_{i,t}$. Avg. COGS-to-OPEX ratio refers to the average of the ratio across firms. Avg. cost-weighted production markup corresponds to the COGS-weighted average markup from Edmond, Midrigan, and Xu (2018). These moments were computed using data from Compustat in 2012. Slope labor prod. on sales corresponds to the OLS coefficient of the sales-weighted regression of relative revenue labor productivity on relative sales from Edmond, Midrigan, and Xu (2018), restricting the sample of firms with relative sales above one. This moment was computed using data from the SUSB in 2012. The average exit rate was obtained from the BDS in 2012. The standard deviation of annual employment growth for continuing establishments is obtained from Elsby and Michaels (2013). Growth rate of variable $x$ is computed as in Davis and Haltiwanger (1992): $(x_{i,t} - x_{i,t-1}) / 0.5(x_{i,t} + x_{i,t-1})$. The last column shows the model counterparts of each moment, which were obtained by simulating a panel of firms and computing each moment with the simulated data. In the model, we account for selection into Compustat by restricting the simulated sample of firms to those that are at least 7 years old and have sales above 19% of the average sales in the simulated economy (which corresponds to the ratio of the 5th percentile of the sales distribution in Compustat to the average sales in SUSB).

Figure 3: Model Fit: Firm Size

Notes: This figure shows moments targeted in the calibration of the model. Panel (a) shows the model fit of the distribution of relative sales. The distribution of relative sales is obtained from the SUSB in 2012. Panel (b) shows the model fit of average employment, relative to 1 year-old firms, by firm age. Average firm employment by age group was obtained from BDS in 2012. In the calibration exercise, we only target the relative size of firms older than 10 years.

the model is able to generate firm dynamics similar to those observed in the data. Second, we
test the model’s predictions regarding the co-movement between a firm’s production markup, average sales per customer and the size of the customer base.

**Firm Dynamics** Figure 4 shows two model-based moments that were not explicitly targeted in the calibration exercise: the average exit rate by age and the average employment growth by age. As Panel A shows, in the model, the average exit rate is decreasing in a firm’s age (as in the data; see e.g., Haltiwanger, Jarmin, and Miranda, 2013). The fact that entrants enter the economy with lower average productivity and no customer base makes young firms more likely to exit when faced with negative productivity shocks due to overhead costs. As firms grow larger, their larger customer base and higher productivity allow them to absorb negative productivity shocks without forcing them to exit. It is important to note that in the firm dynamics literature, the decreasing profile of the average exit rate by age is typically used as a target to indirectly calibrate the size of the overhead cost $\chi$. Here, we took a more direct approach by matching the observed cost structure of firms. The fact that the model replicates the profile of exit rates provides additional support to the modeling of the composition of firms’ cost structures. Panel B plots decreasing profiles of average employment and sales growth as a function of firms’ age. Both patterns are consistent with the empirical evidence in Haltiwanger, Jarmin, and Miranda (2013). For example, in the data, the average net employment growth rate of 1-2 year-old and 7-8 year-old continuing firms is close to 12% and 2.5%, respectively. In the model, the average employment growth rates (computed as in Davis, Haltiwanger, Schuh, et al. (1998)) for 2- and 7-year-old firms are 12.5% and 2.1%, respectively.

![Figure 4: Exit and Growth by Age](image)

**Notes:** Panels (a) and (b) plot model predictions regarding two untargeted moments, the average exit rate by age and the average employment growth by age, respectively.

**Drivers of Firm Growth** We have previously documented that, in the data, the major source of cross-firm differences in sales is the size of their customer bases. Here, we verify the extent to
which the model quantitatively matches this fact. Table 7 compares the variance decomposition of log sales in the model with the decomposition from the data. In the data, differences in the log of average sales per customer account for 11.4% of the variance of log sales. The model closely matches this fact, with a fraction of 15.2%. Also, in the model, the largest contributor to the dispersion in log sales is the variance of the log number of customers, as in the data. However, since differences across firms are ultimately driven by only one source of heterogeneity (i.e., the productivity shocks) the model naturally over-predicts the size of the covariance term.33

Notes: This table provides a variance decomposition of firms’ log sales. The first column reports the variance of the log sales per customer, $\text{var} \left( \ln p_{i,t} \gamma'(p_{i,t}/D_t) \right)$, relative to the overall variance of log sales. The second column reports the relative variance of the log number of customers, $\text{var} \left( \ln m_{i,t} \right)$. The last column reports the covariance between both terms, $\text{cov} \left( \ln m_{i,t}, \ln p_{i,t} \gamma'(p_{i,t}/D_t) \right)$. The first row reports the results obtained from the Nielsen Homescan Panel. Sales and the number of customers are adjusted with household sample weights. The second row reports the results obtained from model simulated data.

Relatedly, we have shown that, despite not being the main driver of sales growth, average sales per customer are strongly associated with market power (see Table 3). Next, we show that our model reproduces this fact quantitatively despite not being a direct target in the calibration. For this, we regress simulated firms’ markups on sales per customer and the size of their customer bases:

$$\ln(\mu_{i,t}) = \theta_0 \ln p_{i,t} q_{i,t} + \theta_1 \ln m_{i,t} + \epsilon_{i,t}.$$  

Table 8 presents the results. The data show a statistically significant relationship between markups and sales per customer and an economically as well as statistically insignificant relationship between markups and the size of the customer base. The model matches these facts fairly well and predicts that 1% higher average sales per customer are associated with 0.11% higher markups. This point estimate is in between the baseline estimate of 0.06 reported in Table 3 and the estimate of 0.187 reported in the additional analysis in Appendix B.3. On the other hand, a 1% increase in the size of the customer base increases markups by only 0.02%.34 Therefore, the model captures the differential roles of intensive and extensive margins of demand

33 The difference between the model and the data could be explained, for instance, by (unmodelled) orthogonal preference shocks that affect the size of the customer base.

34 In our model, the size of the customer base is a demand shifter and does not directly affect the elasticity of demand. The only reason that the regression coefficient on the size of the customer base is not 0 in the model simulated data is a small nonlinear nature of the relationship between these variables.
on firms’ markups, as we document in the data.

Notes: This table reports the results of an OLS regression of a firm’s log markup (ln(\( \mu_{it} \))) on log sales per customer (ln \( p_{it} q_{it} \)) and log size of the customer base (ln \( m_{it} \)). Column (1) reproduces the empirical estimates from Table 3. Column (2) reports estimates based on model-simulated data. The model-simulated panel is restricted to mimic selection into Compustat (see Section 4 for details). In the model, we do not include SIC FE nor Year FE as we model a single “representative” industry in steady-state.

5 The Role of Endogenous Customer Acquisition

This section investigates the role of endogenous customer acquisition in (1) directly shaping a firm’s optimal choices and (2) indirectly determining the aggregate properties of the equilibrium. To do so, we compare the equilibrium allocation of the calibrated model (labeled as “Baseline” from hereon) with the allocation under an alternative model with Kimball demand and without the extensive margin (labeled as “Homogeneous customers” from hereon). This alternative model corresponds to a model in which firms receive a fixed and equal number of total customers in each period without having to spend any resources. We present this comparison in two settings. First, to illustrate how the model works and the mechanisms at play, we provide comparative statics by choosing the same set of parameters across both models while shutting down endogenous customer acquisition in the homogeneous customers one (i.e., \( \phi \to 0 \) and \( \delta = 1 \)). Second, to study the quantitative implications, we recalibrate the homogeneous customers model to the same set of empirical moments (minus the one that pins down returns to advertising \( \phi \)) and compare the implied distribution of markups across the two models.

5.1 Comparative Statics

Implications for Concentration Figure 5 plots the firm dynamics of two entrants that start with productivities equal to the 50th and 99th percentile of the productivity distribution of entrants.
After these initial draws, productivity follows the AR(1) process without further shocks. Panel (a) shows that in the Baseline model (depicted with solid lines), firms frontload their efforts to acquire customers when young with more productive firms spending more on advertising labor, $l_{i,s,t}$. Panel (b) shows that the sales of the more productive firm are larger than the ones of the less productive firm, and also that sales increase initially due to a growing stock of customers but eventually decline due to the mean-reversion of its productivity.

How do firms grow their sales? Panels (c) and (d) of Figure 5 plot the dynamics of the number of customers and sales per customer, respectively. Both firms build their customer base gradually over time due to decreasing returns to advertising. However, sales per customer are higher when firms are younger due to mean-reverting productivity and decreasing marginal product of labor in production. Thus, over time, firms shift their sales strategy from selling more to a few customers, to selling less to more customers.

How does endogenous customer acquisition affect these dynamics? Relative to the Homogeneous customers model (depicted with dashed lines), the more productive firm is able to achieve higher sales by selling less per customer but accumulating more than twice as many customers in the first year. Since more productive firms charge lower prices but higher markups, profits per marginal customer are increasing in productivity, which induces the more productive firms to accumulate customers more rapidly. Given a fixed stock of customers, this can only be possible if firms with lower productivity accumulate fewer customers relative to the Homogeneous customers model. Thus, endogenous customer acquisition increases the dispersion across firms of the number of customers and decreases the dispersion of sales per customer. Table 9 shows that the former effect dominates and the overall concentration of sales increases: While in the Homogeneous customers model, the 5% largest firms capture 17% of sales, in our Baseline model, they capture 50% of sales.

**Implications for Market Power** Table 9 shows that despite higher concentration, the Baseline model features a lower aggregate markup, 1.26 as opposed to 1.38 in the Homogeneous customers model. To understand the sources of this difference, Figure 6 shows the histogram of markups and the scatter plot between markups and relative employment (the weights used in the construction of the aggregate markup) across the two models. These figures illustrate two forces. On the one hand, in the model with endogenous customer acquisition, the distribution of markups is more concentrated. High productivity firms charge lower markups than firms with similar productivity in the Homogeneous customers model. On the other hand, in our model, those high productivity firms account for a larger fraction of total employment.

The following decomposition of the difference in aggregate markups, which follows from
Notes: This figure plots the firm dynamics of two new firms that start with zero customer base and productivities equal to the 50th and 99th percentile of the distribution of productivities among entrants. After this initial draw, firms follow the AR(1) productivity process without any further shock. Solid lines correspond to the “baseline” model. Dashed lines correspond to the “homogeneous customers” model with an exogenous and identical customer base ($m_{i,t} = 1/N_t$). For the latter, we compute the general equilibrium using the calibrated parameters of the baseline model and imposing the parameter restrictions $\phi \to 0$ and $\delta = 1$. Panels (a)-(d) plot the evolution of labor devoted to customer acquisition ($l_{i,s,t}$), sales ($p_{i,t}y_{i,t}$), customer base ($m_{i,t}$) and output per customer ($q_{i,t}$), respectively.

Equation (3.31), quantifies each force:

$$\ln(M_t) - \ln(M_{t}^{HC}) \approx \underbrace{\int_{i \in N} (\omega_{i,t} - \omega_{i,t}^{HC}) \ln(\mu_{i,t}) di}_{\Delta \text{ Distribution: 9.00\%}} + \underbrace{\int_{i \in N^{HC}} \omega_{i,t}^{HC} \left( \ln(\mu_{i,t}) - \ln(\mu_{i,t}^{HC}) \right) di}_{\Delta \text{ Market power: -18.71\%}}.$$

where the superscript $HC$ denotes distributions and allocations in the Homogeneous customers model.\(^{35}\) The first term (denoted “$\Delta$ Distribution”) captures the contribution of differences in the distribution of relative employment (cost-based Domar weights) across firms while keeping firms’ markups fixed at their level in the Baseline model. The second term (denoted “$\Delta$ Market power”) captures the contribution of differences in markups across models while keeping the distribution of relative employment fixed at its distribution in the Homogeneous customers model. As more productive firms charge higher markups, switching the distribution of relative

\(^{35}\)While the equation presents the decomposition based on its approximation for expositional purposes, the numbers we present are computed based on the exact decomposition.
Notes: Panel (a) plots the distribution of production markups in the Baseline and Homogeneous customers models. The vertical dashed lines show the average cost-weighted production markup in each model. Panel (b) shows the scatter plot of relative employment \((l_i,p_t/L_p t/N_t) \propto \omega_{i,t}\) and production markups \(\mu_{i,t}\). The homogeneous customers model refers to the model with an exogenous customer base \((m_{i,t} = 1/N_t)\).

Employment from the Homogeneous customers to the Baseline model increases the average markup by 9pp. However, the contribution of lower markups in the Baseline model reduces the aggregate markup by 18.7pp, so the aggregate markup is on net smaller by 9.71pp. To summarize, why does the baseline model feature a much higher concentration but a lower aggregate markup? Because in the baseline model, firms grow through larger customer bases \(m_{i,t}\), rather than higher average sales per customer \(p_{i,t} q_{i,t}\), which reduces their market power (but increases their lifetime profits).

**Aggregate Implications** Beyond market power, endogenous customer acquisition also affects other aggregate outcomes by concentrating consumers among higher productivity firms. First, relative to the Homogeneous customers model, it allocates more of the economy’s resources towards more productive firms, which reflects itself in higher aggregate TFP derived in Equation (3.28). Table 9 shows that shutting down endogenous customer acquisition in our model reduces aggregate TFP by 28 percent. This is because in the Baseline model, more productive firms utilize a higher share of production resources to meet the demand from their larger customer bases.

Second, the concentration of customers among more productive firms leaves fewer customers for firms at the bottom of the productivity distribution and brings them closer to the exit threshold. Therefore, when we restrict customer bases to be equal across firms, the equilibrium number of firms increases by 65 percent. This additional inflow of firms comes from less productive firms that can now generate positive discounted profits due to a larger (exogenous)
The higher number of firms in the Homogeneous customers also leads to higher demand for employment. Table 9 shows that in the Homogeneous customers model, total employment is 8 percent larger than in the Baseline model (despite the fact that there is no spending on customer acquisition in the former). Part of this difference stems from the larger number of firms, which requires higher overhead costs. Table 9 also shows that aggregate production labor is 6.3 percent larger in the Homogenous customers model. This is the result of income effects that increase labor supply due to lower aggregate consumption. Finally, the changes in aggregate TFP and production labor lead to an overall 24 percent decline in aggregate output.

Notes: The table reports equilibrium aggregates in the baseline and homogeneous customers versions of the model. The homogeneous customers model refers to the model with an exogenous customer base ($m_{it} = 1/N_t$). The second column reports percentage differences with respect to aggregates in the baseline model, with the exception of the aggregate markup and the top 5% sales share, which are reported in levels.

5.2 Recalibrating the Homogeneous Customers Model

As we are interested in the relationship between relative firm size and markups, how would the implied distribution of markups differ if we calibrated both models to the same distribution of firm size? To answer this question, we recalibrate the Homogeneous customers model to the same set of moments that we targeted for the Baseline model, dropping the moment on the relationship between SGA expenses and sales, which was used to pin down returns to advertising, $\phi$. The results of this calibration, as well as results for its goodness of fit, are reported in Appendix G.

The main observation is that by matching the same distribution of sales as in the Baseline model (Figure G.1), the Homogeneous customers model assigns a much lower calibrated value to the parameter determining the super-elasticity of demand ($\eta/\sigma$), similar to the one reported in Edmond, Midrigan, and Xu (2018). The reason for this lower value is that the model is forced
to generate the wide distribution of sales using only the *intensive margin* of demand—i.e., it needs to distribute all firms on the same demand curve. However, since higher $\eta$ diminishes the possibility of selling high quantities to the representative consumer (by generating higher elasticities at higher quantities), the model needs a low value of $\eta$ to match the dispersion of sales in the data. It is important to note that the Baseline model is not constrained by a high value of $\eta$ as it can match the dispersion of sales by placing firms on parallel demand curves using the *extensive margin* of demand.

How does shutting down endogenous customer acquisition distort our interpretation of the data through the lens of the model? As shown in Figure G.2, because of the much lower value of $\eta$, the recalibrated Homogeneous customers model generates much lower markup dispersion relative to our baseline model while matching the same level of cost-weighted markup.\(^{36}\) Two observations follow. First, the Homogeneous customers model overestimates markups for small firms and underestimates markups for large firms relative to our baseline model. Second, by generating a higher markup dispersion than the Homogeneous customers model, the Baseline model implies much higher welfare losses due to misallocation, which we study in the next section.\(^{37}\)

## 6 Quantifying the Efficient Allocation

The objective of this section is twofold. First, we present the differences between the equilibrium and efficient allocations and, in particular, we quantify the gains under the efficient allocation of demand. In doing so, we also revisit our ex-ante decomposition of welfare in Proposition 5 and quantify the contribution of each of the three channels (TFP, Aggregate Markups and Overhead costs).

Second, in order to isolate the role of endogenous customer acquisition, we repeat our first exercise for counterfactual values of $\phi$—the parameter that governs the proximity of the equilibrium allocation of customers to the Pareto frontier—and study how welfare losses change once the equilibrium distribution of customers gets closer to the efficient allocation.

**Gains in Welfare** We start by quantifying the three channels of welfare gains from Proposition 5 in our calibrated model:

---

\(^{36}\)Recall that with $\eta = 0$, the Kimball aggregator converges to the CES aggregator and markup dispersion is zero.  
\(^{37}\)In the Compustat data, the overall dispersion of markups is larger than the dispersion obtained from either our Baseline model or the Homogeneous customers model. This is expected since our model focuses only on the dispersion of markups that arises from differences in relative sales (per customer). In reality, markups or wedges in marginal revenue of products can arise due to other distortions (see e.g., *Hsieh and Klenow, 2009*) from which our model abstracts away.
\[
\frac{\Delta U_t}{U_{c,t} C_t} \approx \Delta \ln(Z_t) - \alpha \mathcal{M}_t^{-1} \frac{N_t}{L_{p,t}} \Delta \ln(N_t) + \alpha (1 - \mathcal{M}_t^{-1}) \Delta \ln(L_{p,t})
\]

\(\Delta\text{Welfare (C.E.)} = 13.6\% \quad \text{TFP gains} = 10.8\% \quad \text{Gains from Entry/Exit} = 1.6\% \quad \text{Losses from Underutilization of Labor} = 0.78\%

There are two main takeaways from this decomposition: (1) the consumption-equivalent welfare gains of the household under the efficient allocation are substantial and quantified at 13.6\%, (2) the majority of this gain is coming from the efficiency gains in aggregate TFP under the planner’s allocation, quantified at 10.8\% higher than the equilibrium TFP. In addition to this substantial gain in TFP, the planner also achieves 1.6\% higher welfare by reducing the amount of labor allocated towards the overhead cost of operating firms and 0.78\% higher welfare by correcting for the underutilization of labor due to aggregate market power.

Moreover, the ‘Baseline’ column in Table 10 presents the implied changes in other quantities that arise from these gains. As a result of a higher TFP and a higher production labor, output is 14.6\% higher under the efficient allocation despite the fact that the number of firms is 11.3\% lower. This higher production with fewer firms is made possible by the fact that concentration of sales among the top 5\% largest firms is 39.2\% larger than in the equilibrium. In addition to the baseline model, Table 10 also presents similar results for two counterfactual values of \(\phi\). In the remainder of this section, we dissect these changes and study the underlying forces that shape these gains.

<table>
<thead>
<tr>
<th>Table 10: Comparison with Efficient Allocation</th>
</tr>
</thead>
</table>
| \(\begin{array}{l}
\text{Endogenous } m_{i,t} \\
\phi = 0.25 \quad \text{Baseline} \quad \phi = 0.75
\end{array} \) |
| \hline |
| TFP | 24.1 | 10.8 | 3.2 |
| Output | 27.5 | 14.6 | 7.7 |
| Number of firms | -41.9 | -11.3 | -2.6 |
| Employment | -5.0 | 2.1 | 4.4 |
| Production | 5.3 | 6.0 | 7.0 |
| Welfare | 37.9 | 13.6 | 4.0 |
| Agg. markup | -27.8 | -22.8 | -19.1 |
| Top 5\% sales share | 88.8 | 39.2 | 15.5 |
| \hline |

Notes: The table compares aggregate variables between the social planner’s allocation and the equilibrium allocation. Differences are reported as percent deviations from equilibrium allocations. Three comparisons are presented by varying the value of \(\phi\), while keeping the remaining parameters fixed at the values in the baseline calibration.

Implications for Misallocation: By explicitly modeling the extensive margin of demand, in a way consistent with the data, we find large TFP gains of 10.8\%. This shows that efficiency losses
from misallocation of customers are large and go well beyond the social costs of markups (for instance, Edmond, Midrigan, and Xu (2018) estimate the efficiency losses from markups to be around 0.8% to 1.8%).

To further analyze the increase in aggregate productivity, we consider the decomposition of TFP derived in Baqaee and Farhi (2019) and separate the allocative efficiency gains from technological change. For us, allocative efficiency refers to how differently the planner allocates resources across firms, while technological change is a manifestation of the different entry and exit policies that the planner adopts. Formally, let $Z(N_t, A_t)$ denote the aggregate productivity implied by the set of operating firms $N_t$ with an allocation rule $A_t \equiv (l_i, p, t)_{i \in N_t}$ among them. Then, we can decompose the difference in TFPs across two allocations as

$$
\ln \left( \frac{Z(N^*_t, A^*_t)}{Z(N_t, A_t)} \right) = \ln \left( \frac{Z(N^*_t, A^*_t)}{Z(N_t, A^*_t)} \right) + \ln \left( \frac{Z(N^*_t, A^*_t)}{Z(N^*_t, A^*_t)} \right) .
$$

(6.2)

The first term on the right-hand side of Equation (6.2) shows that, keeping the set of operating firms fixed, almost 75% of the efficiency gains under the planner’s allocations are due to allocative efficiency gains. This is the most important consequence of endogenous customer acquisition: Having the ability to reallocate customers across firms, the planner shifts the distribution of customers towards the top of the productivity distribution, and hence is able to allocate higher amounts of production labor towards them.

The extensive margin of demand is the key to the high TFP gains in our model: without the extensive margin, the planner can only achieve a higher aggregate productivity by shifting demand towards more productive firms on the intensive margin. However, since varieties are weak substitutes, distorting the distribution of relative demand is costly. These costs are even higher when demand is more elastic at higher quantities (as with Kimball preferences or any semi-kinked demand system).

However, in this model, the efficient allocation is not restricted by the weak substitutability margin: Completely equalizing relative consumption across individuals ($q^*_{i,t} = 1$), the efficient allocation achieves much higher aggregate productivity by simply allocating more customers towards more productive firms ($m^*_{i,t} \propto z^{1/\sigma}_{i,t}$)—as seen in Figure F.8, which shows a comparison of the allocation of customers between the equilibrium and the efficient allocation. As a consequence of this reallocation of customers, the concentration of sales among the top 5% of firms increases by 39.2%. This higher concentration of customers among more productive firms is efficient to the point that marginal costs of production are equalized across all firms.

It is important to note that the efficient allocation of customers across firms is not restricted by the decreasing returns to scale in advertising, even though the planner is subject to the same advertising technology as in the equilibrium. This follows from the fact that the planner
internalizes the business-stealing externalities of advertising, and by Lemma 6 can implement any desired distribution of customers given the same equilibrium technology.

Finally, while the optimal allocation of resources accounts for around 75% of the change in aggregate TFP, the remaining 25% is explained by sheer compositional changes in the distribution of productivity, i.e., technological change. Under the efficient allocation, the planner is more selective in allowing firms to enter and chooses a higher productivity cutoff for entry and exit of firms. A more selective policy increases TFP because it increases the average productivity of firms that operate in the economy and implies a fewer number of operating firms.

The Optimal Number of Firms We start by reviewing the usual costs and benefits of having more firms in the economy and then discuss the new mechanism that comes into play in our model. In conventional models, the optimal number of firms are affected by the interaction of three forces: decreasing returns to scale, love for variety, and aggregate overhead costs. On one side, with decreasing returns to scale at the firm level, having more firms increases the aggregate efficiency by dividing resources across a larger number of firms. Moreover, with love for variety, even fixing the average output produced by a larger set of firms, the household enjoys the resultant aggregated output more and hence the economy experiences a higher productivity. While these forces form the benefits of a higher number of firms, the cost is usually modeled either as a fixed entry cost for every firm or, as we model here, a stream of overhead costs over time, both of which lead to an optimal finite measure of firms in the equilibrium.

Moreover, our model has an additional force that arises from the allocation of customers across firms. Since the number of customers is fixed, a higher concentration of customers at the top comes at the cost of fewer customers at the bottom of the productivity distribution, which in turn reduces the social value of such firms (as shown in Proposition 8). Hence, with this additional instrument, our planner achieves a higher TFP without having to pay for the overhead costs of more firms, which leads to a lower number of firms in the efficient allocation and increases the welfare of the household by 1.6% as shown in Equation (6).

Aggregate Labor Supply Two forces work in opposite directions in affecting the differences of aggregate labor supply between the efficient and equilibrium allocations. On the one hand, the more selective policy of the planner for entry and exit reduces the amount of labor required for financing the overhead costs of operating firms. On the other hand, production labor is underutilized in the equilibrium due to the aggregate market power of firms. The ‘Baseline’

---

38 Both of these forces can be summarized by the following simple example inspired by Edmond, Midrigan, and Xu (2018). Consider an economy with $N$ firms indexed by $i$, where every firm produces with $y_i = l_i^\alpha$ and aggregate output is given by a CES aggregator, $Y = \int_0^N y_i^\theta \, di$. For a given amount of aggregate labor, $L$, every firm gets to produce $y_i = (L/N)^\alpha$ and the aggregate output is given by $Y = N^{\theta-\alpha} L^\alpha$. Now if we shut down love for variety ($\theta = 1$), productivity is $N^{1-\alpha}$ which increases with $N$. If we shut down decreasing returns to scale ($\alpha = 1$), productivity is $N^{\theta-1}$ indicating higher productivity due to love for variety with larger $N$. 

45
column of Table 10 shows that while labor allocated towards production goes up by 6% under the efficient allocation, which together with the higher aggregate TFP contributes towards the 14.6% increase in output, the aggregate labor goes up only by 2.1%, as it is mitigated by the lower use of labor in financing the entry cost of firms.

**The Role of Returns to Scale in Marketing** While, for the planner, the only relevant margin in allocating customers is the returns to scale in production, the efficiency gains from reallocation of customers depend on the returns to scale for customer acquisition, $\phi$. A larger returns to scale in customer acquisition would imply that more productive firms would invest more in customer acquisition, which is desirable from the perspective of the efficient allocation. Figure 7 shows the scatter plot of firms’ productivity and output for both the equilibrium and social planner’s allocation and for three different values of $\phi$ (a low value, the calibrated value and a high value). The figure shows that with a larger $\phi$ the equilibrium allocation of customers is closer to that of the planner.\(^{39}\)

![Figure 7: Allocation of Output: Equilibrium vs. Efficient Allocation](image)

**Notes:** This figure shows a scatter plot between relative productivity $z_{i,t}/\bar{z}$ and relative output $y_{i,t}/\bar{y}$, for both the equilibrium and the social planner’s allocation. We present three plots by varying the value of $\phi$, while keeping the remaining parameters fixed at the values in the baseline calibration. Low $\phi$ corresponds to 0.25, baseline to 0.53, and high to 0.75.

Finally, the $\phi = 0.25$ and $\phi = 0.75$ columns of Table 10 show how the allocation of customers is solely responsible for the large efficiency gains under the planner’s allocation. By simply allowing $\phi$ to be larger, the equilibrium welfare losses drop from 38% in the case of $\phi = 0.25$ to only 4% with $\phi = 0.75$. When $\phi$ is larger, in the equilibrium, more productive firms grow mainly through

\(^{39}\)In fact, for a the special case of $\delta = 1$, the allocation of customers in the equilibrium coincides with the efficient allocation when $\phi \to 1$. 

46
acquiring more customers (higher $m$) rather than selling more per customer (higher $q$). As a result, they produce for more customers but sell less per customer, and as a result, charge lower markups. Hence, aggregate TFP, output, and concentration increase while the aggregate markup decreases and the economy gets closer to the efficient allocation.

7 Conclusion

In this paper, we revisit the role of the extensive and intensive margins of demand in firms’ market share and market power. Using a dataset that merges information from the consumer and the producer sides, we document that while firms’ sales grow mainly through acquiring more customers, their market power is only correlated with their average sales per customer. Moreover, we find that firms’ non-production costs are associated with their customer acquisition but not customer retention or sales per customer.

Guided by these empirical findings, we develop and quantify a model that micro-founds the relationship between market power and concentration in the extensive and intensive margins. In our model, while firms hold market power over each customer, the total number of customers acts as a demand shifter. The model provides a new perspective on the relationship between relative firm size and market power. Firms that are big due to a larger customer base have lower market power relative to equally big firms with higher sales per customer. We also find substantive welfare gains under the efficient allocation that stems from the new Pareto frontier of the economy under endogenous customer acquisition.

Our analysis sheds light on the effectiveness of policies that target market power through concentration and profits. In particular, our model highlights a new unintended consequence from policies that target only firms’ market power. In our model, although market power is distortionary, it compensates more productive firms for their investment in customer acquisition and improves the allocation of customers. Thus, policies that target larger firms disproportionately may have adverse effects through the misallocation of customers. In particular, if more productive firms are taxed for their larger sales due to larger customer bases, on the margin, they will sell to fewer customers at lower prices but higher markups—both of which are inefficient from a social perspective

APPENDIX FOR ONLINE PUBLICATION

A Further data description

This section further describes the process to clean the Nielsen and Compustat data used in this paper. For this, we follow the previous studies that use these two datasets (Hottman, Redding, and Weinstein 2016 for Nielsen and De Loecker, Eeckhout, and Unger 2020; Traina 2019 for Compustat).

A.1 Nielsen and GS1: Variables and Data Cleaning

We construct the following variables from the Nielsen Homescan Panel, Promodata, and GS1 company data:

- **UPC**: scanner-level product identifier available in Nielsen Homescan Panel and Promodata.
- **GS1 Company Identifier**: GS1 company id. GS1 provides both UPC and firm identifiers along with company name and headquarter location. This information allows us to identify firm boundaries in the Nielsen data and further merge the data with Compustat.
- **Sales**: We define sales as the sum of the total expenditures of households at different levels of aggregation: UPC-year, firm-year, and group-firm-year. We use sample weights (projection factor) to make the Nielsen household sample representative at the national level.
- **Number of Customers**: For each firm, product (UPC), or group-firm, we aggregate the number of households with the sample weight adjustment.
- **Sales per Customer**: At each level of aggregation, we define average sales per customer as total sales divided by the number of customers.

**Sample Selection of Homescan Panel data**

The Homescan Panel data we use covers 2004-2016.

1. Following Neiman and Vavra (2019), we balance the product modules across years to exclude the effect of entry and exit of modules, which mainly arises from name changes and potentially adds measurement error.
2. To make the sample representative, we drop “magnet products” in Nielsen data which are fresh produce and other items without barcodes.
3. We drop products that do not have a product group identifier to make the analysis consistent across different specifications.
4. There is a small number of observations for which the sampling year of the household is different than the year when their purchases took place. They reflect the fact that households were sampled in late December. While the corresponding purchases are recorded as the current year, their household panel years are recorded as the following year. We drop these observations to use coherent sample weights across households and years.

We restrict the sample in the Promodata to the years 2006-2011 since the data is incomplete for the other years. Following this data's manual, we use both active and inactive files and drop the duplicated observations in inactive files. We adjust for multi-package and unit size in utilizing the UPC-level information; we do the same when we merge in price information from Homescan Panel data. We exclude the small number of markets that are not common across the Homescan Panel and Promodata.
A.2 Compustat: Variables and Data Cleaning

We download and construct the following variables from Compustat:

- **Global company key** (mnemonic gvkey): Compustat’s firm id.
- **Year** (mnemonic fyear): the fiscal year.
- **Selling, general and administrative expense** (mnemonic XSGA): the SG&A sums “all commercial expenses of operation (such as, expenses not directly related to product production) incurred in the regular course of business pertaining to the securing of operating income.” They include expenses such as marketing and advertising expenses, research and development, accounting expenses, delivery expenses, etc.
- **Costs of goods sold** (mnemonic COGS): the COGS sums all “expenses that are directly related to the cost of merchandise purchased or the cost of goods manufactured that are withdrawn from finished goods inventory and sold to customers.” They include expenses such as labor and related expenses (including salary, pension, retirement, profit sharing, provision for bonus and stock options, and other employee benefits), operating expense, lease, rent, and loyalty expense, write-downs of oil and gas properties, and distributional and editorial expenses.
- **Operating expenses, total** (mnemonic XOPR): OPEX represents the sum of COGS, SG&A and other operating expenses.
- **Sales (net)** (mnemonic SALE): this variable represents gross sales, for which “cash discounts, trade discounts, and returned sales and allowances for which credit is given to customer” are discounted from the final value.
- **Capital**: we calculate capital in two ways. First, we simply set capital to be equal to the gross property, plant and equipment value (mnemonic PPEGT) deflated by the investment goods deflator from NIPA’s nonresidential fixed investment good deflator (line 9). For our second measurement of capital, we use the perpetual inventory method—we set the first observation of each firm to be equal to the gross property, plant and equipment value and for subsequent years we add the difference from \( netPPE_t \) (mnemonic PPENT) and \( netPPE_{t-1} \). We also deflate the difference in PPENT by the investment goods deflator from NIPA’s nonresidential fixed investment good deflator.
- **Company’s initial public offering date** (mnemonic IPODATE).
- **Age**: given that the initial public offering date was missing for a large portion of our dataset, we calculated age as the fiscal year of a given observation minus the first year that we observe a firm in the dataset. According to Compustat, a firm enters the dataset after it starts providing consistent accessible annual reports trading on a U.S. exchange market, i.e. after its IPO. Following Haltiwanger, Jarmin, and Miranda (2013), we exclude the first fifteen years of the dataset for all analyses using age and we group together firms older than sixteen years, because we do not know for certain a firm’s IPO date for firms that were in the Compustat data since the first year.

We used NIPA Table 1.1.9. GDP deflator (line 1) to generate the real value for the variables sale, COGS, XOPR, and XSGA.

**Sample Selection** We downloaded the dataset “Compustat Annual Updates: Fundamentals Annual,” from Wharton Research Data Services, from Jan 1950 to Dec 2016. The following options were chosen:

- Consolidated level: C (consolidated)
We took the following steps for the cleaning process:

1. To select American companies, we filtered the dataset for companies with Foreign Incorporation Code (FIC) equal to “USA.”
2. We replace industry variables (sic and naics) by their historical values whenever the historical value is not missing.
3. We drop utilities (sic value in the range [4900, 4999]) because their prices are very regulated and financials (sic value in the range [6000,6999]) because their balance sheets are exceptionally different than the other firms in the analysis.
4. To ensure quality of the data, we drop missing or non-positive observations for sales, COGS, OPEX, sic 2-digit code, gross PPE, net PPE, and assets. We also exclude observations in which acquisitions are more than 5% of the total assets of a firm.
5. A portion of the data missing for sales, COGS, OPEX, and capital in between years for firms. We input these values using a linear interpolation, but we do not interpolate for gaps longer than two years. This exercise inputs data for 4.6% of our sample.

A.3 The Coverage of the Nielsen-Compustat Sample

There are approximately 300 firms identified in Compustat that can be matched with the Nielsen data in 2004-2016. Although the number of firms we matched is small, they account for a significant fraction of total sales, number of UPCs, and observations in the Nielsen Homescan Panel data, as shown in Table A.1.

Table A.1: The Coverage of the Nielsen-Compustat Sample

<table>
<thead>
<tr>
<th></th>
<th>Sales (b)</th>
<th># of UPCs (k)</th>
<th># of Obs. (m)</th>

Note: Sales is the projection-factor weighted sales in Nielsen data and is denoted in billions US dollars. # of UPCs is in thousand UPCs, and # of Obs. is in millions of observations. All variables are annual averages.
B  Additional Empirical Results

This section provides additional results to confirm the robustness of our main empirical findings.

B.1  Firm Sales Growth Decomposition

One concern in Figure 1 is that some firms might only appear temporarily in our data not because of their actual behavior but due to sampling error. For example, it could be that households in our sample do not appear to purchase a firm’s product even though the product was actually purchased and not recorded. In this case, the average value of sales, number of customers, and sales per customer of young firms in our analyses might be confounded with those of old firms.

To address the concern of the sampling error, Figure B.1 uses only those firms that appear at least three or five consecutive years. The results still show that the number of customers is a primary factor that generates an increase in firms’ sales over time. There is a steeper increase in sales in the firm’s early-stage than our baseline results in Figure 1. The results are intuitive since firms that survive for several years are likely to generate more sales at the beginning relative to firms that could not survive. Overall, the robustness analysis suggests that the sampling errors are not the first-order concerns in our analyses.

Figure B.1: Decomposition of Firm Sales Growth by Firm Age: Survivors

Notes: Figures B.1a and Figure B.1b replicate Figure 1 by using the firms that appear in the sample for at least 3 and 5 consecutive years, respectively. There are 32,242 number of observations and 6,400 firms used in Figures B.1a and 19,603 number of observations and 2,997 firm used in Figure B.1b.

Another concern is that firms might sell their products in a different number of months over the following years. For example, some firms might enter the market in late November or December but sell their products over many months in the subsequent years. To adjust for these differences, we calculate the average monthly sales over a year per firm and redo the decomposition exercise in Figure B.2. There is a smaller increase in firms’ sales at age 1, suggesting that some firms enter during the late months of the initial year. However, the relative importance of the number of customers in explaining sales remains the same, accounting for approximately 70% of sales on average.

Also, one might be worried that the empirical pattern we observe might not apply to the products outside of our sample, which is restricted to products with a barcode. For example, it
could be that for more durable products that customers purchase occasionally, firms might not be able to grow as much through the extensive margin of demand because they may not face the same customers every year.

Given that there is no other consumer-producer matched dataset (to the best of our knowledge), we utilize our data—which covers a substantial fraction of consumer goods with a wide variety of products—to understand the underlying differences between durable and non-durable products. We closely follow Argente, Lee, and Moreira (2019) and define the product group-level durability by using the information on the number of shopping trips. We count the average yearly number of trips customers made to purchase products in each product group and divide product groups into durable and non-durable products based on the median value of average trips. The set of durable products include, for example, “LIGHT BULBS, ELECTRIC GOODS”, “HARDWARE, TOOLS”, and “AUTOMOTIVE”, and the non-durable products include “MILK”, “SNACKS”, and “BEER”.

Figures B.3a and Figure B.3b replicate Figure 1 by dividing firms based on the durability of products they sell. There are 19,988 observations and 5,050 firms used in Figures B.3a and 29,816 observations and 7,323 firms used in Figure B.3b.
Figure B.3 presents the results. Regardless of analyzing durable or non-durable products, firms mainly grow by expanding their customer bases. The relevance of the number of customers for firm growth remains when redefining durable goods based on the 75th percentile of the trips distribution or analyzing the variance decomposition of total sales of durable or non-durable products.

### B.2 Markups, Sales per customers, and Sales

Table B.1 replicates Table 3 by replacing the number of customers with a firm’s total sales. We replace the number of customers with sales, so that our regressors have the same unit. Regardless of whether we control for total sales or the number of customers, our results show a strong correlation between markups and sales per customer, suggesting the importance of sales per customer in understanding firm-level markups.

Notes: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$; standard errors are clustered at the firm-level. Markups are measured as Sales-to-COGS ratio. SIC is a two-digit SIC code, and all Nielsen variables are projection-factor adjusted.

### B.3 Evidence Based on Product-level Markups

This section revisits our analysis of the relationship between markups and the relative size of different margins of a firm’s demand by combining two alternative approaches to measure price-cost markup and account for marginal costs. Our baseline analysis focuses on firm-level markups and public firms. Here, we show that we find similar results when expanding the scope to product-level markups and analyzing a much broader set of firms in the Nielsen data.

As a first alternative approach, we use the difference between the retail-level price and the wholesale cost at the product level to measure markups. For this, we use microdata on the UPC-market-year-level wholesale cost from the Nielsen PromoData available through the Chicago Booth Kilts Center. The PromoData records wholesale costs by UPC, market, and year and is collected from 12 national wholesalers in the period 2006-2012 (we restrict our sample to the years 2006-2011 since there is a substantial number of missing observations in 2012). In total, we use data from 45 markets (examples of markets are Chicago, Los Angeles, and Atlanta). Given that the data lacks detailed sales information, we take a simple geometric average of wholesale costs by UPC, market, and year after adjusting for the package size. We then (1)
combine this information with the retail-level price, sales, and sales per household from the Nielsen Homescan Panel data and (2) measure the retail-level markup at the product (UPC) level as the difference between the retail price and the wholesale cost (we drop negative values of the measured markups). A similar approach has been followed by Gopinath, Gourinchas, Hsieh, and Li (2011) and Stroebel and Vavra (2019).

This measure of markups assumes that other costs, such as wages and capital expenditures, do not confound the observed relationship among markups, average sales per customer, and the number of customers. However, there could exist sources of variation in marginal costs across retailers as well, in addition to the variation arising from differences in product-level wholesale costs. To alleviate these concerns, we exploit the rich variation in the data and control for such differences in marginal costs by incorporating various sets of fixed effects in the regression, as the approach followed by Fitzgerald, Haller, and Yedid-Levi (2016). Our markup measure could vary at the UPC, year, market, and retailer level, so we progressively include different combinations of fixed effects at those levels to absorb differences in marginal costs that could potentially confound the relationship of interest. For example, the fact that retailers sell the same UPC in multiple locations allows us to control for differences in marginal costs at the retailer-year-UPC level. The underlying assumption is that the retailer's marginal cost of selling a given UPC is the same across markets. Similarly, we can account for any time-invariant costs by including a set of UPC-market-retailer fixed effects and any differential distribution costs by incorporating a set of UPC-market-year fixed effects. The final sample contains data from 7,802 UPCs, 45 markets, 6 years, and 167 retailers.

Table B.2 confirms our previous results regarding the relationship among markups, average sales per customer, and the number of customers reported in Table 3. Column (1) shows that markups are strongly positively correlated with average sales per customer. The relationship between markups and the number of customers is negative but an order of magnitude smaller in size. Column (2) includes UPC-, market-, and retailer-fixed effects interacted with year-fixed effects. We find similar results, although the coefficients become smaller (in absolute value). Columns (3), (4), (5), and (6) allow for additional sets of fixed effects that absorb any differences in marginal costs at those levels (including the variation in wholesale costs, which is at the UPC-market-year-level). Once we exploit the geographical variation in the data and include retailer-year-UPC fixed effects in column (3), the coefficient on the number of customers declines to -0.016, while the coefficient on the average sales per customer remains stable at 0.166. Controlling for time-invariant costs in column (4) shows similar changes in the coefficients: There is still a positive and significant relationship between markups and average sales per customer, but no economically significant relationship with the number of customers (the coefficient is estimated close to zero). Adding the additional sets of fixed effects in columns (5) and (6) shows similar relationships among variables. Table B.3 replaces the number of customers in Table B.2 with total sales so that our two main regressors are expressed in the same unit. These results confirm that the relevant margin for the relationship between relative size and markups is the average sales per customer.

B.4 Sales and SGA Expenses: Decomposition by Durability of Products

Using the same durability measure we constructed and used in Figure B.3, we analyze the potential heterogeneity in the relationship between SGA expenses and sales by a product’s durability. Table B.4 reports the results. We find no statistically significant differences in this relationship by the durability of products.

B.5 Sales and the Components of SGA Expenses

This section revisits the correlation of sales and SGA expenses by analyzing the sub-components of the latter. In the main body of the paper, we rely on total SGA expenses as the main cost variable since it is reported for almost all the firms in the dataset. To be more explicit on the nature of these expenses, we further investigate the sub-components of SGA expenses that are available for a subset of our sample. Among all the components reported in the data, the ones that are strongly correlated with firms’ sales are related to expansionary activities: advertising (e.g., awareness of the existence of products/firms) and rent expenses (geographical proximity). We analyze these expansionary components to provide further evidence on the correlation between SGA expenses and sales.

Tables B.5 and B.6 show the correlation between sales and its components with advertising and rent expenses, respectively. Both tables show the same empirical relationship reported in Table 4: The correlation between sales and the expansionary components of SGA costs arises from the correlation with the number of customers and, in particular, with the acquisition of new customers. Overall, these results corroborate the empirical evidence of endogenous customer acquisition.\(^{40}\)

\(^{40}\)For the particular case of R&D expenses, which could also be interpreted as an expansionary activity, the point estimates obtained are similar in magnitude to the ones reported in Tables B.5 and B.6. However, the small fraction of firms reporting these expenses decreases the precision of the estimates.
Our analysis also reveals that other components of SGA (such as Foreign Exchange Income, Staff Expense, Receivables, and State Income Taxes) are not correlated with sales (results nor reported), consistent with the view that total SGA expenses correlate with a firm’s sales through their expansionary components.

### B.6 The Semi-variable Nature of SGA

This section establishes that the SGA expenses have a semi-variable nature and correlate with firms’ short-run sales. Previous studies that examined the non-production cost of firms (SGA) made polar opposite assumptions on the variable nature of this cost. For instance, in measuring price-cost markups, Traina (2019) includes non-production costs as variable costs, whereas De
Loecker, Eeckhout, and Unger (2020) interprets non-production costs as fixed costs in their baseline approach. We empirically assess the validity of such assumptions by comparing the co-movement of sales and SGA expenses with the co-movement of sales and other costs that are commonly assumed to be variable and fixed in the short-run in the literature: COGS expenses and investment.

Figure B.4: The Semi-variable Nature of SGA

(a) Restricted Sample

(b) Full Sample

Notes: The figure shows the binned scatter plot of the correlation between the quarterly change in log sales and the quarterly change in i) log SGA expenses, ii) log COGS expenses, and iii) log stock of capital for firms in the quarterly Compustat dataset. We also plot the best linear fit for each variable. The correlations control for quarter and firm fixed effects. In Panel (a), we restrict the sample to observations with a change in the log of sales between -0.1 and +0.1 (the 25th and 75th percentiles of the quarterly change of log sales is -8% and 11%, respectively). Panel (b) plots the binned scatter plot using the full sample. We adapt the perpetual inventory method following Traina (2019) and use Gross and Net Capital (PPEGT and PPENT) and deflate investment with NIPA’s non-residential fixed investment good deflator to measure the capital stock. There are 17,168 firms in the 1964-2016 period used in this analysis.

Our results suggest that SGA expenses have both variable and fixed components; it is more variable than the capital expenditure but less than COGS expenses. Figure B.4a reports the binned scatter plot of changes in sales against changes if firm’s costs for a range of $\Delta \ln S_{i,t}$ between -10% and 10%, which are approximately the 25th and 75th percentiles of the $\Delta \ln S_{i,t}$ distribution. Consistent with the view in the literature (e.g., De Loecker, Eeckhout, and Unger 2020), sales exhibit the largest co-movement with production costs ($\beta = 0.894$; SE 0.008), and the lowest co-movement with investment ($\beta = 0.081$; SE 0.008). Figure B.4b shows that similar relationships hold in the full sample.

We consider other empirical specifications to confirm the semi-variable nature of SGA expenses. Table B.7 presents the regression results that correspond to Figure B.4. The semi-variable nature of SGA expenses is clear in this table, both with and without fixed effects. We also show that R&D expenses (a sub-component of SGA costs) are more variable than the stock of capital but less variable than total SGA expenses. Finally, Figure B.5 reports the coefficients of a regression of SGA expenses on leads and lags of total sales, which further supports the short-run variability of SGA expenses: Although there is a strong correlation between SGA expenses and contemporaneous sales, we find no large correlation with future or past sales.

C  Model with Heterogeneous Tastes and Sorting

In this section, we provide two model extensions to our households’ preferences. In the first, we allow for idiosyncratic preference shocks that affect the optimal quantities consumed by each consumer. In the second, we allow for shifters that affect the perceived “quality” of each variety. We discuss how each extension affects the total demand of a firm as well as the relationship between the number of customers and average sales per customer. We also provide empirical evidence for why we abstract away from these extensions in the main analysis.

C.1  Taste for Quantity

Consider the following extension of the Kimball aggregator in Equation (3.1):
\[
\int_0^{N_t} \int_0^1 1_{j \in m_{i,t}} \xi_{i,j,t}^{-1} Y \left( \frac{c_{i,j,t} C_t}{C_t} \right) \, d j \, d i = 1, \tag{C.1}
\]
where \( \xi_{i,j,t} \) is now household \( j \)’s “quantity” taste for variety \( i \) at time \( t \). The implied relative demand for firm \( i \) at \( t \) is then given by
\[
\frac{c_{i,t}}{C_t} = \frac{m_{i,t}}{\text{number of customers}} \times \mathbb{E}[\xi_{i,j,t} | j \in m_{i,t}] Y^{-1} \left( \frac{p_{i,t}}{D_t} \right), \tag{C.2}
\]
where \( \mathbb{E}[\xi_{i,j,t} | j \in m_{i,t}] \) is the average quantity taste of firm \( i \)’s customers. The introduction of such shocks will affect firm \( i \)’s demand depending on the nature of sorting between customers and firms. If there is no sorting or selection in who is matched to a firm, then \( \mathbb{E}[\xi_{i,j,t} | j \in m_{i,t}] = \mathbb{E}[\xi_{i,j,t}] \) and this extension replicates the demand function in the main text. However, sorting generates a correlation between the number of customers and average sales per customer. For example, with positive sorting, firms with a larger customer base should sell less per customer on average (because the marginal customer always buys less than the average customer). Instead, with negative sorting (e.g., when marginal consumers are the ones who experiment with the product and buy more than the average consumer), firms with a larger customer base should sell more per customer on average. More generally, this model implies the following relationship between average sales per customer and a firm’s number of customers
\[
\ln(p_{i,t} q_{i,t}) = \beta_0 \ln(m_{i,t}) + \ln \left( p_{i,t} Y^{-1} \left( \frac{p_{i,t}}{D_t} \right) \right), \tag{C.3}
\]
where the sign and magnitude of \( \beta_0 \) determine the type and strength of sorting, respectively. To test this, we aggregate the Nielsen Homescan Panel data at the UPC-year-level. For this analysis, we use the whole sample available in Homescan Panel data. We compute the price of each product as sales divided by the unit-adjusted quantity. Table C.1 shows the results of OLS regressions of the log average sales per customer of UPC \( u \) at time \( t \) on the log number of customers and polynomials of log price that approximate the nonlinear function \( Y^{-1}(\cdot) \). Across all specifications, we consistently find a small and positive relationship between the size of the customer base and average sales per customer. Firms with a 1% higher number of customers sell on average 0.03% more per customer. Given the economic insignificance of this estimate, we do not consider this kind of preference heterogeneity in our model, which as discussed below is a conservative choice.
Table C.1: Average Sales per Customer and The size of the Customer Base

Notes: * p < 0.10, ** p < 0.05, *** p < 0.01; Standard errors are clustered by product group. The variable p_{ut} q_{ut} denotes the sales per customer of UPC u at time t, m_{ut} is the number of customers, and p_{ut} is the price.

Implications of Sorting for Misallocation Results
A potential concern in our analysis of efficiency losses from the misallocation of demand is that sorting of customers might exacerbate or reduce welfare losses from misallocation. For example, since with positive sorting, the marginal customer values a variety less than the average customer, the marginal value of allocating customers to more productive firms might not be as high as in our baseline model. However, regression results in Table C.1 show that, if anything, there is a negative, albeit small, sorting (i.e., the marginal customer buys more than the average customer). Viewed through the lens of this model extension, these results indicate that the quantified welfare losses from misallocation of demand in Section 6 provide a lower bound on the actual welfare losses once this small negative sorting is taken into account.

C.2 Taste for Quality
Another source of preference heterogeneity can be the different perception of the “quality” of a variety across customers. For this, consider the following extension of the Kimball aggregator in Equation (3.1):

\[ \int_0^{N_t} \int_0^1 \mathbb{1}_{\{j \in m_{i,t}\}} \zeta_i, j, t \gamma \left( \frac{c_{i,j,t}}{C_t} \right) d j d i, = 1 \]  

where \( \zeta_{i,j,t} \) is now the household j’s “quality” taste for variety i at time t. We assume for any i and t that \( \zeta_{i,j,t} \) is i.i.d. and its distribution is scaled so that its unconditional mean is 1 (\( \mathbb{E}[\zeta_{i,j,t}] = 1 \)).

The implied relative demand of firm i is then given by

\[ q_{i,t} = \frac{c_{i,t}}{C_t} = \int_0^1 \mathbb{1}_{\{j \in m_{i,t}\}} \gamma^{t-1} \left( \frac{p_{i,t}}{\zeta_{i,j,t} D_t} \right) d j. \]  

The curvature of \( \gamma^{t-1}(\cdot) \), and thus the elasticity of demand, now interacts with the distribution of \( \zeta_{i,j,t} \). However, we can show that up to a first-order approximation, sorting would imply a correlation between average demand per customer and the number of customers, similar to the one derived for quantity shocks. To see this, note that up to a first-order approximation around
the point \( \frac{p_{i,t}}{\mathbb{E}[\zeta_{i,j,t} \mid D_t]} \):

\[
\Upsilon^{t-1} \left( \frac{p_{i,t}}{\zeta_{i,j,t} D_t} \right) \approx \Upsilon^{t-1} \left( \frac{p_{i,t}}{D_t} \right) (1 + \sigma_{i,t}(\zeta_{i,j,t} - 1)),
\]

where \( \sigma_{i,t} \) is the elasticity of demand evaluated at the average quality taste, \( p_{i,t}/D_t \), and hence depends only on the price. Now, using this approximation we can write demand as

\[
\frac{c_{i,t}}{C_t} \approx \frac{m_{i,t}}{\text{number of customers}} \times \Upsilon^{t-1} \left( \frac{p_{i,t}}{D_t} \right) (1 + \sigma_{i,t}(\mathbb{E}[\zeta_{i,j,t} \mid j \in m_{i,t}] - 1)),
\]

where \( \mathbb{E}[\zeta_{i,j,t} \mid j \in m_{i,t}] \) is the average quality taste of firm \( i \)'s customers. Similar to quantity shocks, if there is positive (negative) sorting, then \( \mathbb{E}[\zeta_{i,j,t} \mid j \in m_{i,t}] \) is a decreasing (increasing) function of \( m_{i,t} \) and we should see a negative (positive) relationship between \( q_{i,t} \) and \( m_{i,t} \), which brings us to the same argument in the previous section for quantity shocks.
D Derivations and Proofs

D.1 Lemma 1

Proof. We start from the expression for the optimal price of the firm:
\[
\ln \left( \frac{p_{i,t}D_t}{D_t} \right) = \ln(\varepsilon_{i,t}) - \ln(\varepsilon_{i,t} - 1) + \ln \left( \frac{mc_{i,t}}{D_t} \right),
\]
where
\[
\varepsilon_{i,t} = -\frac{\partial \ln(q_{i,t})}{\partial \ln(p_{i,t})} = \frac{\sigma}{1 - \eta \ln(p_{i,t}) + \eta \ln(D_t(1 - \sigma^{-1}))}.
\]
The last equality in Equation (D.2) follows from the expression of demand per match in Equation (3.9). Differentiating Equation (D.1) we have:
\[
d \ln \left( \frac{p_{i,t}D_t}{D_t} \right) = (1 - \mu_{i,t})d \ln(\varepsilon_{i,t}) + d \ln \left( \frac{mc_{i,t}}{D_t} \right) = \frac{1}{1 + \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)}d \ln \left( \frac{mc_{i,t}}{D_t} \right),
\]
where \( \mu_{i,t} = \frac{\varepsilon_{i,t}}{\varepsilon_{i,t} - 1} \geq 1 \) is the firm's markup. Then, it follows that
\[
d \ln(\mu_{i,t}) = d \ln(p_{i,t}) - d \ln(mc_{i,t}) = -\frac{\eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)}{1 + \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)}d \ln \left( \frac{mc_{i,t}}{D_t} \right).
\]
Restricting \( d \ln(D_t) = 0 \) and considering partial changes in \( \ln(mc_{i,t}) \)—e.g., moving in the cross-section of firms towards firms with higher marginal costs within a particular time when \( D_t \) is fixed—gives us the expressions of interest. The sign restrictions follow from \( \mu_{i,t} \geq 1 \) and \( \varepsilon_{i,t} \geq 0 \).

D.2 Proposition 2

Proof. Consider the sales per match of firm \( i \) normalized by the demand index \( D_t \), \( p_{i,t}q_{i,t}/D_t \). Differentiating the log of this quantity, we have
\[
d \ln \left( \frac{p_{i,t}q_{i,t}D_t}{D_t} \right) = (1 - \varepsilon_{i,t})d \ln \left( \frac{p_{i,t}D_t}{D_t} \right) = -\frac{\varepsilon_{i,t} - 1}{1 + \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)}d \ln \left( \frac{mc_{i,t}}{D_t} \right).
\]
Therefore, combining this expression with Equation (D.3), we have
\[
d \ln(\mu_{i,t}) = \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1)d \ln \left( \frac{p_{i,t}q_{i,t}}{D_t} \right).
\]
Again, restricting \( d \ln(D_t) = 0 \) and considering partial changes in sales per customer—e.g., moving in the cross-section of firms towards firms with higher sales per customer within a particular period when \( D_t \) is fixed—we get:
\[
\frac{d \ln(\mu_{i,t})}{d \ln(p_{i,t}q_{i,t})} \bigg|_{d \ln(D_t)=0} = \eta \sigma^{-1} \varepsilon_{i,t}(\mu_{i,t} - 1) \geq 0
\]
where the sign restriction follows from \( \mu_{i,t} \geq 1 \).

D.3 Corollary 3

Proof. Recall that a firm's relative total sales within a period is given by
\[
\frac{\int_{i \in N_t} p_{i,t}Y_{i,t} \, di}{\int_{i \in N_t} p_{i,t}Y_{i,t} \, di/C_t} = \frac{p_{i,t}Y_{i,t}}{C_t} = p_{i,t}q_{i,t}m_{i,t}.
\]
Now, restricting \( p_{i,t}, y_{i,t}/C_t = \bar{s} \), we have
\[
0 = d \ln (p_{i,t}, y_{i,t}) \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}} = d \ln (p_{i,t}, q_{i,t}) \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}} + d \ln (m_{i,t}) \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}} \quad (D.8)
\]
\[
\Rightarrow d \ln (p_{i,t}, q_{i,t}) \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}} = -d \ln (m_{i,t}) \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}}. \quad (D.9)
\]
Now, using Equation (D.6) we have
\[
\frac{\partial \ln (\mu_{i,t})}{\partial \ln (m_{i,t})} \bigg|_{p_{i,t}, y_{i,t}/C_t = \bar{s}} = -\frac{\partial \ln (\mu_{i,t})}{\partial \ln (p_{i,t}, q_{i,t})} = -\eta \sigma^{-1} \mu_{i,t} (\mu_{i,t} - 1) \leq 0, \quad (D.10)
\]
where the sign restriction follows from \( \mu_{i,t} \geq 1 \).

**D.4 Proposition 4**

*Proof.* This relationship is obtained directly from the first order condition of the firm's problem with respect to \( m_{i,t} \). For the rest of the proof, we derive this first order condition.

We start by showing that the firm's customer acquisition constraint always binds (meaning that the firm never disposes of its existing customers). To show this, note that it cannot be the case that \( l_{i,s,t} > 0 \) but \( m_{i,t} < (1 - \delta) m_{i,t-1} + \frac{\dot{r}_{i,s,t}}{p_{m,t}} \) since the firm can keep the same \( m_{i,t} \) with a lower \( l_{i,s,t} \). Thus, if \( m_{i,t} < (1 - \delta) m_{i,t-1} + \frac{\dot{r}_{i,s,t}}{p_{m,t}} \), then optimality requires that \( l_{i,s,t} = 0 \). Now, suppose \( l_{i,s,t} = 0 \) but \( m_{i,t} < (1 - \delta) m_{i,t-1} \). Note that in this case, the slope of the firm's "production" profit function with respect to \( m_{i,t} \) is given by
\[
\frac{\partial}{\partial m_{i,t}} (p_{i,t}, y_{i,t} - W_t l_{i,p,i}) = (p_{i,t} - m c_{i,t}) \frac{y_{i,t}}{m_{i,t}} > 0, \quad (D.11)
\]
where the last equality follows from the fact that for any choice of \( q_{i,t} > 0 \), the firm's markup is always strictly larger than 1 and hence \( p_{i,t} > m c_{i,t} \). Thus, the firm's profit is strictly increasing in \( m_{i,t} \) and since \( m_{i,t} < (1 - \delta) m_{i,t-1} \), then the firm can increase its \( m_{i,t} \) at no cost and gain more profits at time \( t \). Moreover, this will not affect firms' profits in the future since the firms can always dispose of the increase in \( m_{i,t} \) in the next period at no cost. Hence, optimality requires that \( m_{i,t} = (1 - \delta) m_{i,t-1} + \frac{\dot{r}_{i,s,t}}{p_{m,t}} \).

Now, in writing firm \( i \)'s problem at time \( t \), replace \( l_{i,p,i} = (y_{i,t}/z_{i,t})^{\alpha^{-1}} \), \( y_{i,t} = m_{i,t} q_{i,t} C_t \), and \( l_{i,s,t} = P_{m,t}^{-1} (m_{i,t} - (1 - \delta) m_{i,t-1})^{\phi^{-1}} \) to obtain the problem as
\[
\max_{(p_{i,t}, m_{i,t}, q_{i,t}, l_{i,t}) \geq 0} \mathbb{E}_t \sum_{\tau \geq t} (\beta^{\gamma})^{\tau-t} C_{\tau}^{-\gamma} \left( \prod_{h=t}^{\tau} 1_{i,h} \right) \times
\]
\[
\left[ p_{i,t} m_{i,t} q_{i,t} C_t - W_t \left( \frac{m_{i,t} q_{i,t} C_t}{z_{i,t}} \right)^{\alpha^{-1}} - W_t P_{m,t}^{-1} (m_{i,t} - (1 - \delta) m_{i,t-1})^{\phi^{-1}} - W_t \lambda \right]
\]
\[
\text{s.t.} \quad q_{i,t} = \left[ 1 - \eta \ln \left( \frac{p_{i,t}}{D_t (1 - \sigma^{-1})} \right) \right]^{\eta} \cdot
\]

Next, if \( 1_{i,t} = 0 \), then \( l_{i,s,t} = 0 \). However, conditional on \( 1_{i,t} = 1 \), the FOC with respect to \( m_{i,t} \) is
\[
0 = 1_{i,t} (p_{i,t} - \alpha^{-1} \frac{W_t l_{i,p,i}}{y_{i,t}}) q_{i,t} C_t - 1_{i,t} \dot{\phi}^{-1} \frac{W_t l_{i,s,t}}{m_{i,t} - (1 - \delta) m_{i,t-1}}
\]

68
\[+ \beta v(1-\delta) \mathbb{E}_t \left[ \left( \frac{C_{t+1}}{C_t} \right)^{1-\gamma} \mathbf{1}_{i,t+1} \phi^{-1} \frac{W_{t+1} l_{i,s,t+1}}{m_{i,t+1} - (1-\delta) m_{i,t}} \right].\]

Replacing \( m_{i,t} = \alpha^{-1} \frac{W_{i,t} p_{i,t}}{y_{i,t}} \) and iterating the FOC forward gives us the expression of interest. \( \square \)

**D.5 Proposition 5**

**Proof.** Let \((C_t, L_p, L_s, L_t, N_t)_{t \geq 0}\) denote the equilibrium allocation. A log-linearization of \(U(C_t, L_t) = \frac{C_t^{1-\gamma}}{1-\gamma} - \xi L_t^{1+\psi}\) around this allocation gives:

\[
\Delta U(C_t, L_t) = C_t^{1-\gamma} \Delta \ln(C_t) - \xi L_t^{1+\psi} L_{p,t} \Delta \ln(L_{p,t}) + \frac{L_{s,t}}{L_{p,t}} \Delta \ln(L_{s,t}) + \frac{N_t}{L_{p,t}} \Delta \ln(N_t) + \mathcal{O}(\|\|^2).
\] (D.12)

Next, divide by \(U_{c,t} C_t = C_t^{1-\gamma}\) and use the household’s optimal labor supply condition \(\xi \frac{L_t^{\psi}}{C_t} = W_t\) to get

\[
\frac{\Delta U(C_t, L_t)}{U_{c,t} C_t} = \Delta \ln(C_t) - \frac{W_t L_{p,t}}{C_t} \Delta \ln(L_{p,t}) + \frac{L_{s,t}}{L_{p,t}} \Delta \ln(L_{s,t}) + \frac{N_t}{L_{p,t}} \Delta \ln(N_t) + \mathcal{O}(\|\|^2).
\] (D.13)

Finally, using the aggregate production function in Equation (3.27), replace \(\Delta \ln(C_t) = \Delta \ln(Z_t) + \alpha \Delta \ln(L_{p,t})\), and, using the definition of the aggregate markup in Equation (3.31), replace the labor share in terms of the cost-weighted markup \(\frac{W_t L_{p,t}}{C_t} = \frac{\alpha}{\Lambda_t}\) to get

\[
\frac{\Delta U(C_t, L_t)}{U_{c,t} C_t} \approx \Delta \ln(Z_t) + \alpha (1-\Lambda_t^{-1}) \Delta \ln(L_{p,t}) - \alpha \Lambda_t^{-1} \frac{L_{s,t}}{L_{p,t}} \Delta \ln(L_{s,t}) + \frac{N_t}{L_{p,t}} \Delta \ln(N_t).
\] (D.14)

**D.6 Planner’s Problem**

The Planner’s problem for this economy is given by

\[
\max_{\{\{c_{i,j,t}\}_{j \in [0,1]} \mid \{i,j\} \in N_{t-1} \cup N_t\}, \{\delta_{i,t} m_{i,t}, l_{i,p,t}, l_{i,s,t} \} \in N_{t}, c_{i,t}\}_{t \geq 0}} \sum_{t=0}^{\infty} \beta^t \left[ \frac{C_t^{1-\gamma}}{1-\gamma} - \xi L_t^{1+\psi} \right]
\] (D.15)

subject to

\[
\int_0^1 1_{\{j \in m_{i,t}\}} \mathbf{1}_{i,j,t} d j = z_{i,t} \mathbf{1}_{i,p,t}, \quad \forall i \in N_t,
\] (D.16)

\[
\int_{i \in N_t} \int_0^1 1_{\{j \in m_{i,t}\}} \gamma \left( \frac{c_{i,j,t}}{C_t} \right) d j d i = 1
\] (D.17)

\[
\int_{i \in N_t} (l_{i,p,t} + l_{i,s,t} + \chi) d i = L_t
\] (D.18)

\[
\int_{i \in N_t} m_{i,t} d i = 1
\] (D.19)

\[
N_t = \{i \in N_{t-1} \cup \Lambda_t: 1_{i,t} \mathbf{1}_{i,t} = 1\}, \quad N_{t-1} \text{ given.}
\] (D.20)

\[
m_{i,t} = (1-\delta_{i,t}) m_{i,t-1} + \frac{1 - \int_{i \in N_t} (1-\delta_{i,t}) m_{i,t-1}}{\int_{i \in N_t} l_{i,s,t}^\phi} l_{i,s,t}, \quad \forall i \in N_t,
\] (D.21)

\[
\delta_{i,t} \in [\delta, 1], l_{i,s,t} \geq 0, \quad \forall i \in N_t,
\] (D.22)
Here, Equation (D.16) requires that for every firm, their supply meets their allocated demand, Equation (D.17) is the Kimball aggregator that implicitly defines $C_t$ given the planner allocation of demand, Equation (D.18) requires that labor supply meets demand for labor from production, advertisement and overhead costs, Equation (D.19) requires that the matching market clears, Equation (D.20) is the law of motion for the set of operating firms given an entry/exit policy by the planner, Equation (D.21) determines firm $i$’s evolution of customers given an allocation for advertising, Equation (D.22) requires the non-negativity of labor for advertising and the constraint that while the planner can separate customers from firms the separation rate should be at least $\delta$, and finally Equation (D.23) requires that the planner at least spends $\bar{L}_{s,t}$ on advertisement. This last constraint is for an arbitrary but a strictly positive $\bar{L}_{s,t}$—in Lemma 6 we show that the level of this quantity does not matter for the optimal distribution of customers, which is also well-defined in the limit when $\bar{L}_{s,t} \to 0$.

D.7 Lemma 6

Proof. Suppose that at any given time $t$, a choice for $N_t$ is fixed. Suppose next that the planner desires to allocate matches according to a rule

$$\mathcal{A} : (i \mapsto m^*_{i,t})_{i \in N_t}. \tag{D.24}$$

Note that this can be any arbitrary allocation of matches as long as it is feasible:

$$m^*_{i,t} \geq 0, \quad \forall i \in N_t \tag{D.25}$$

$$\int_{i \in N_t} m^*_{i,t} di = 1. \tag{D.26}$$

To show that the allocation $\mathcal{A}$ is implementable on $N_t$ for any given level of $\bar{L}_{s,t}$, we need to show that (1) it is generated by a choice of $(\delta_i \leq 1, l_{i,s,t} \geq 0)_{i \in N_t}$, and (2) it is feasible $\int_{i \in N_t} l_{i,s,t} di = \bar{L}_{s,t}$. We show this by construction. In particular, consider the choice:

$$\left( \delta^*_{i,t} = 1, l^*_{i,s,t} = \bar{L}_{s,t}, \frac{m^*_{i,t}}{\int_{i \in N_t} m^*_{i,t} di} \right)_{i \in N_t}. \tag{D.27}$$

That is, first, let the planner separate all the matches from their corresponding firms ($\delta^*_{i,t} = 1$) and then reallocate them based on $\mathcal{A}$. It follows that Equations (D.25) and (D.26) from above hold by construction. Next, to verify that these values implement $\mathcal{A}$, observe that

$$m_{i,t} \equiv (1 - \delta_{i,t}) m_{i,t-1} + \left(1 - \int_{i \in N_t} (1 - \delta_{i,t}) m_{i,t-1} di \right) \frac{l_{i,s,t}^{\phi}}{\int_{i \in N_t} l_{i,s,t}^{\phi} di} = m^*_{i,t}. \tag{D.28}$$

Finally, to confirm feasibility, note that $\int_{i \in N_t} l^*_{i,s,t} di = \bar{L}_{s,t}$. \hfill \blacksquare

D.8 Proposition 7

Proof. To prove this Proposition, we proceed in two steps. First, we characterize the optimal demand per customer and the allocation of customers for a given set of operating firms, $N_t$, over time. Second, we show that the optimal allocation for these two objects maximizes the aggregate TFP, given $N_t$, subject to feasibility constraints for $(q_{i,t}, m_{i,t})_{i \in N_t}$.
Moreover, throughout this proof we rely on the result from Lemma 6 and directly characterize the distribution of matches \( m_{i,t} \) ignoring the constraints in Equations (D.21) and (D.22) as well as Equation (D.23). Having characterized this distribution, we can then use the result from Lemma 6 to find the allocation of advertisement labor that implements it.

**Step 1: Optimal Allocation of Demand.** The results in this Proposition follow from the first-order conditions of the planner’s problem in Equation (D.15), fixing the planner’s other choices at an arbitrary allocation. In the remainder of this proof, we characterize these first-order conditions.

Formally, for firm \( i \) and period \( t \), let \( \beta^t \varphi_{c,i,t} di \) be the shadow cost on Equation (D.16); for period \( t \), let \( \beta^t \varphi_{Y,t} \), \( \beta^t \varphi_{L,t} \) and \( \beta^t \varphi_{m,t} \) be the shadow costs on Equation (D.17), Equation (D.18) and Equation (D.19), respectively. Moreover, similar to the equilibrium allocation, let us define \( q_{i,j,t} \equiv \frac{c_{i,j,t}}{C_i} \). It is straightforward to show that for \( j \not\in m_{i,t} \), \( q_{i,j,t} = 0 \). So from here on forward we only refer to \( q_{i,j,t} \) when \( j \in m_{i,t} \).

The first order conditions with respect to \( q_{i,j,t} \) are

\[
\varphi_{c,i,t} C_t = Y'(q_{i,j,t}) \varphi_{Y,t}, \quad \forall j \in m_{i,t}.
\] (D.29)

It immediately follows that all households that are matched to a variety consume the same amount:

\[
q_{i,j,t} = q_{i,t}, \quad \forall j \in m_{i,t}.
\] (D.30)

Replacing this result in Equation (D.16) and Equation (D.17) and taking the first order condition with respect to \( m_{i,t} \), we have:

\[
\varphi_{c,i,t} q_{i,t} C_t + \varphi_{m,t} = Y(q_{i,t}) \varphi_{Y,t}.
\] (D.31)

Notice that in deriving this first order condition, we have ignored the constraint in Equation (D.21). The reason that we can do this goes back to Lemma 6, which states that any choice of \( (m_{i,t})_{i \in N_t} \) can be implemented without any loss of generality. Therefore, we can ignore the constraint in Equation (D.21) and then use Lemma 6 to show that it is satisfied.

Next, replacing Equation (D.30) in Equation (D.29), multiplying it by \( q_{i,t} \) and subtracting it from Equation (D.31), we have:

\[
\varphi_{m,t} = \left[ Y(q_{i,t}) - q_{i,t} Y'(q_{i,t}) \right] \varphi_{Y,t}.
\] (D.32)

Since \( \varphi_{Y,t} \neq 0 \), it follows that

\[
Y(q_{i,t}) - q_{i,t} Y'(q_{i,t}) = \frac{\varphi_{m,t}}{\varphi_{Y,t}}, \quad \forall i \in N_t.
\] (D.33)

Notice that the left hand side of this equation is only a function of \( q_{i,t} \) and it is strictly monotonic in \( q_{i,t} > 0 \). Moreover, the right hand side of the equation is only a function of time-\( t \) shadow costs and is independent of \( i \). Hence, there exists a unique \( q_{i,t}^* \) such that

\[
q_{i,t} = q_{i,t}^* \quad \forall i \in N_t.
\] (D.34)

---

\(^{41}\)To see why, suppose not. Then, by Equation (D.29), either \( C_i = 0 \)—which is clearly not optimal since marginal utility approaches infinity as \( C_i \to 0 \)—or \( \varphi_{c,i,t} = 0 \)—which means that the household can freely supply infinite labor to firm \( i \) at \( t \) and is also a contradiction since it violates the positive disutility of the labor supply.

\(^{42}\)Observe that \( D_x[Y(x) - Y'(x)x] = -Y''(x)x > 0 \).
Replacing this last equation into Equation (D.17) we have:

\[ \int_{i \in N_t} m_{i,t} Y(q^*_i) di = 1 \Rightarrow Y(q^*_i) = 1 \Rightarrow q^*_i = 1, \quad (D.35) \]

where the second statement uses the market clearing condition for matches in Equation (D.19) and the last statement uses the strict monotonicity of \( Y(x) \) and the fact that \( Y(1) = 1 \).

Given that the social planner sets \( q_{i,t} = 1 \) for all firms, it implies that firms’ productions will differ under the efficient allocation only through different numbers of customers. To determine the optimal level of production, we only need to consider the FOC with respect to \( l_{i,p,t} \):

\[ \alpha \varphi_{c,i,t} z_{i,t} l_{i,p,t}^{\alpha-1} = \varphi_{L,t}. \quad (D.36) \]

Dividing this equation by the first order condition for \( m_{i,t} \) in Equation (D.29), we get

\[ z_{i,t} l_{i,p,t}^{\alpha-1} = \frac{C_t}{\alpha Y'(1) \varphi_{Y,t}}. \quad (D.37) \]

Solving for \( l_{i,p,t} \) from this equation and replacing it Equation (D.16) we have

\[ \int_{j \in m_{i,t}} c_{i,j,t} d j = m_{i,t} C_t = z_{i,t} \left( \frac{C_t}{z_{i,t} \alpha Y'(1) \varphi_{Y,t}} \right)^{\frac{1}{\alpha-1}} \Rightarrow m_{i,t} = \left( \frac{z_{i,t}}{C_t} \right)^{\frac{1}{\alpha-1}} \left( \frac{\varphi_{L,t}}{\alpha Y'(1) \varphi_{Y,t}} \right)^{\frac{1}{\alpha-1}}. \quad (D.38) \]

Finally, imposing the market clearing condition for matches in Equation (D.19) we get

\[ m_{i,t} = \frac{\frac{1}{z_{i,t}^{\frac{1}{\alpha}}}}{\int_{i \in N_t} \frac{1}{z_{i,t}^{\frac{1}{\alpha}}}} di, \quad \forall i \in N_t. \quad (D.39) \]

**Step 2: Optimal Demand Allocation Maximizes Aggregate TFP.** First, let us derive aggregate TFP. Consider an allocation of \( l_{i,p,t} \) across firms in \( N_t \). Then, aggregate production labor is given by

\[ L_{p,t} = \int_{i \in N_t} l_{i,p,t} di = \int_{i \in N_t} \left( \frac{C_t \int_{j \in m_{i,t}} q_{i,j,t} d j}{z_{i,t}} \right)^{\frac{1}{\alpha-1}} d i \quad (D.40) \]

where the second equality follows from the fact that for every firm demand must meet supply. Rearranging this gives us an expression for TFP as function of demand allocation within \( N_t \):

\[ C_t = \left[ \int_{i \in N_t} \left( \frac{z_{i,t}}{\int_{j \in m_{i,t}} q_{i,j,t} d j} \right)^{-\alpha-1} d i \right]^{-\alpha} \times L_{p,t}^{\alpha}. \quad (D.41) \]

Now, maximizing \( Z_t \) is equivalent to minimizing \( Z_t^{-\alpha} \). Thus, the problem of maximizing \( Z_t \) subject to Kimball aggregator becomes:

\[ \min_{\{q_{i,j,t}\}_{i,j \in m_{i,t}}} \int_{i \in N_t} \left( \int_{j \in m_{i,t}} q_{i,j,t} d j \right)^{-\alpha} d i \quad (D.42) \]

\[ s.t. \int_{i \in N_t} \int_{j \in m_{i,t}} 1_{\{j \in m_{i,t}\}} q_{i,j,t} d j d i = 1 \]

\[ \int_{i \in N_t} \int_{j \in m_{i,t}} 1_{\{j \in m_{i,t}\}} d j d i = 1 \quad (D.44) \]
First, fix an allocation for $m_{i,t}$. Notice that since $\alpha^{-1} > 1$, the objective function is convex in each $q_{i,j,t}$ for any $j \in m_{i,t}$ so the FOC for $q_{i,j,t}$ is sufficient for optimality. Allowing $\eta_{Y,t}$ and $\eta_{m,t}$ to be the multipliers on Equations (D.43) and (D.44), the FOC for $q_{i,j,t}$, $j \in m_{i,t}$ reads

$$\frac{1}{\alpha z_{i,t}} \left( \int_0^1 1_{[j \in m_{i,t}]} q_{i,j,t} d j \right) \alpha^{-1} - \eta_{m,t} = Y'(q_{i,j,t})$$  \hspace{1cm} (D.45)

since the left hand side of this equation depends only on firm/time level variables, it follows that all the consumers in the $m_{i,t}$ consume the same $q_{i,j,t}$; i.e., $q_{i,j,t} = q^*_{i,j,t}$ where $q^*_{i,j,t}$ solves the above equation. Substituting this into the objective we can re-write the choice of $m_{i,t}$ as simply choosing the size the customer base for firms, which with slight abuse of notation we also denote as $m_{i,t}$. Formally,

$$\int_0^1 1_{[j \in m_{i,t}]} q_{i,j,t} d j = m_{i,t} q^*_{i,t}$$  \hspace{1cm} (D.46)

Again, it is straightforward to see that the objective is convex in $m_{i,t}$ and the first order condition for it reads:

$$\frac{q^*_{i,t}}{\alpha z_{i,t}} \left( \frac{m_{i,t} q^*_{i,t}}{z_{i,t}} \right) \alpha^{-1} - \eta_{m,t} = Y(q^*_{i,t}) \eta_{Y,t}$$  \hspace{1cm} (D.47)

Subtracting the first order condition for $m_{i,t}$ from the first order condition for $q_{i,j,t}$ we arrive at

$$\frac{\eta_{m,t}}{\eta_{Y,t}} = Y(q^*_{i,t}) - q^*_{i,t} Y'(q^*_{i,t})$$  \hspace{1cm} (D.48)

Note that the right hand side is a monotonic function of $q^*_{i,t}$ (since $Y$ is increasing and concave) and the left hand side does not depend on $i$. So $q^*_{i,t} = q^*_{i}$ for some $q^*_{i}$. Substituting $q_{i,j,t} = q^*_{i,t}$ in Equation (D.43) then yields that $Y(q^*_{i}) = 1$ which implies $q^*_{i} = 1$. Substituting this into the FOCs and using the constraints we then retrieve the optimal $m^*_{i,t}$ as

$$m^*_{i,t} = \frac{1}{\int_{j \in N_i} z_{i,j,t}^{\frac{1}{\alpha}}} d i$$  \hspace{1cm} (D.49)

Hence, choosing the allocation of demand to maximize the aggregate TFP gives the optimal allocation of demand under the social planner’s problem. 

**D.9 Proposition 8**

**Proof.** Our goal here is to derive the social value of a firm that enters the economy at a certain point in time. To do so, we start by writing a (partial) Lagrangian for the planner’s problem and rearrange it to isolate all the terms in the Lagrangian that are related to a particular firm. In writing this Lagrangian, we utilize two of the results that we have established so far. First, given our result in Lemma 6, we ignore the constraints in Equations (D.21) and (D.22) as well as Equation (D.23). Instead, we can allow the social planner to directly choose the distribution of matches at any given time and use the results in the proof of Lemma 6 to substitute for the optimal advertisement labor. Second, to make the comparison to the equilibrium value of firms natural, we take advantage of Equation (D.30) which establishes that the social planner chooses the same $q_{i,j,t}$ for all the households that are matched to firm $i$ at time $t$. Aside from these two
results, however, we refrain from imposing any other optimality conditions at the firm level to maximize the comparability of the firms’ social value with their equilibrium value.

Thus, we can form the following partial Lagrangian for the social planner (with the Lagrange multipliers defined as in Appendix D.8):

$$\max_{\{1, t\} \in N_{t-1} \cup \Lambda_t, \{N_t \setminus N_i, \Lambda_t \}} \sum_{t=0}^{\infty} \beta^t \left[ \frac{C_t^{1-\gamma}}{1-\gamma} - \xi_L 1+\psi \left( \int_{i \in N_t} m_{i,t} Y(q_{i,t}) - 1 \right) + \varphi_{Y,t} \left( \int_{i \in N_t} m_{i,t} Y(q_{i,t}) - 1 \right) \right]$$

(D.50)

subject to the constraints in Equation (D.16) (i.e., demand meets supply) and Equation (D.20), which captures the law of motion for the set of firms active in the economy. To rearrange this partial Lagrangian in a way that it resembles the problem of the firms in the equilibrium, consider the following two operations: first, rearrange the terms within the brackets to put all the integrals of the form $\int_{i \in N_t} di$ in one bracket. Second, factor out $\varphi_{Y,t}$ from these integrals. These two operations lead to the following expression for the partial Lagrangian:

$$\max_{\{1, t\} \in N_{t-1} \cup \Lambda_t, \{N_t \setminus N_i, \Lambda_t \}} \mathbb{E}_{0} \sum_{t=0}^{\infty} \beta^t \left[ \frac{C_t^{1-\gamma}}{1-\gamma} - \xi \frac{L_t^{1+\psi}}{1+\psi} - \varphi_{Y,t} + \varphi_{L,t} \left( L_t - \tilde{L}_{s,t} + \chi \right) \right]$$

$$+ \mathbb{E}_{0} \sum_{t=0}^{\infty} \beta^t \int_{i \in N_t} \varphi_{Y,t} \left( m_{i,t} Y(q_{i,t}) - \frac{\varphi_{L,t}}{\varphi_{Y,t}} (l_{i,t} + \chi) \right) \left( 1 - \int_{i \in N_t} m_{i,t} d i \right)$$

(D.51)

The second line is what we are after, once we switch the order of the sum and the integration: Since this expression first integrates over the set of all operating firms at time $t$ and then sums over time, we can isolate the contribution of every firm to this Lagrangian separately by switching the order of integration and summation. In doing so, we will take advantage of the law of motion for the set $N_t$, Equation (D.20), as a function of the planner’s choice for entry/exit of firms as well as endogenous exit shocks. Formally, pick a firm $i$ that enters the economy for the first time at time $t$ (i.e., $t = \min_{t \geq 0} \{1 \setminus N_t \}$ with $t \equiv 1$ indicating firms that were in the initial distribution of firms in the economy). Then, $i$ will be in any $N_t$ for $t \geq t$ as long as $\prod_{h=t}^{t} v_{i,t} 1_{i,h} = 1$. Therefore, the second line in the equation above can be written as

$$\mathbb{E}_{0} \sum_{t=0}^{\infty} \beta^t \int_{i \in N_t} \varphi_{Y,t} \left( m_{i,t} Y(q_{i,t}) - \frac{\varphi_{L,t}}{\varphi_{Y,t}} (l_{i,t} + \chi) - \frac{\varphi_{m,t}}{\varphi_{Y,t}} m_{i,t} \right) d i$$

(D.52)

$$= \mathbb{E}_{0} \sum_{t=0}^{\infty} \beta^t \int_{i \in \tilde{\Lambda}_t} \mathbb{E}_{t} \sum_{\tau=t}^{\infty} (\beta \psi)^{T-\tau} \left( \prod_{h=t}^{T} 1_{i,h} \right) \varphi_{Y,t} \left( m_{i,t} Y(q_{i,t}) - \frac{\varphi_{L,t}}{\varphi_{Y,t}} (l_{i,t} + \chi) - \frac{\varphi_{m,t}}{\varphi_{Y,t}} m_{i,t} \right) d i,$$

(D.53)

where $\tilde{\Lambda}_0 = \Lambda_0 \cup N_{t-1}$ and $\tilde{\Lambda}_t = \Lambda_t$ for all $t \geq 1$.

Finally, substituting Equation (D.52) into Equation (D.51), we arrive at the following reformulation of the social planner’s problem:
we can write:

\[
\max_{(C_{i,t})_{t \in \mathbb{N}}} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left\{ C_t^{1-\gamma} - \xi L_t^{1+\psi} - \varphi_{Y,t} + \varphi_{L,t} (L_t - \tilde{I}_{s,t}) + \varphi_{m,t} \right\} + \varphi_{Y,t} \int_{\mathbb{N}} \max_{\{q_{i,t}, l_{i,p}, \tau \}} \mathbb{E}_t \sum_{\tau \in \mathbb{T}} (\beta \nu)^{\tau-t} \left( \prod_{h=1}^{\tau} \mathbb{1}_{i,h} \right) \frac{\varphi_{Y,t}}{\varphi_{Y,t}} \left( \frac{m_{i,t} \epsilon Y(q_{i,t}) - \varphi_{L,t}}{\varphi_{Y,t}} (l_{i,p} + \chi) - \frac{\varphi_{m,t}}{\varphi_{Y,t}} m_{i,t} \right) d\tau
\]

Social Value of Firm \( i \equiv G_{i,t} \)

\[ (D.54) \]

s.t. \( m_{i,t} q_{i,t} C_t = z_{i,t} l_{i,p,t}^a, \quad \forall i \in \mathbb{A}_t, \forall \tau \geq t, \]

where \( G_{i,t} \) is the culmination of all the terms in the social planner’s problem in which a firm \( i \) shows up and thus captures the value of the firm for the planner.

To compare \( G_{i,t} \) to the equilibrium value of the firm, the final step is to relate the Lagrange multipliers to aggregate objects that are similar to the equilibrium wage \( W_t \) and demand index \( D_t \). Let us derive the first-order conditions for the aggregate consumption \( C_t \) and aggregate labor supply \( L_t \). For \( C_t \), we get:

\[
C_t^{* \gamma} = \varphi_{c,i,t} \int_{\mathbb{N}_t} m_{i,t}^* q_{i,t}^* d\tau = \varphi_{Y,t} \int_{\mathbb{N}_t} m_{i,t}^* q_{i,t}^* Y'(q_{i,t})^* d\tau C_t^{-\gamma},
\]

where stars denotes that these equations hold under the optimal choice of these variables and the right hand side follows from substituting the FOC for \( c_{i,j,t} \) from above. Moreover, note that the integral on the right hand side is exactly how we defined the demand index in the equilibrium.

So let us define it similarly for the social planner as

\[
D_t^* = \left[ \int_{\mathbb{N}_t} m_{i,t}^* q_{i,t}^* Y'(q_{i,t})^* \right]^{-1} \Rightarrow \varphi_{Y,t} = C_t^{* \gamma} D_t^*.
\]

Furthermore, the FOC for \( L_t \) gives: \( \xi L_t^{* \gamma} = \varphi_{L,t} \). If we define the notion of the “wage” for the planner as the marginal rate of substitution between leisure and consumption, \( W_t^* \equiv \xi L_t^{* \gamma} C_t^{* \gamma} \), we can write:

\[
\frac{\varphi_{L,t}}{\varphi_{Y,t}} = \frac{W_t^*}{C_t^* D_t^*}.
\]

Now, to derive an expression for \( \varphi_{m,t}/\varphi_{Y,t} \), we use Equation \((D.33)\). Multiplying both sides of that equation with \( m_{i,t} \) and integrating over the set \( N_t \), we arrive at:

\[
\frac{\varphi_{m,t}}{\varphi_{Y,t}} = \int_{\mathbb{N}_t} m_{i,t} Y(q_{i,t}) d\tau - \int_{\mathbb{N}_t} m_{i,t} q_{i,t} Y'(q_{i,t}) d\tau = 1 - D_t^{-1}.
\]

The last step in comparing \( G_{i,t} \) to the equilibrium value of firms defined in Equation \((3.15)\) is to make their units consistent. The equilibrium value of a firm entering at time \( t \) in Equation \((3.15)\) is defined in the units of aggregate consumption at time \( t \), where \( G_{i,t} \) is in time \( t \) utils; to convert time \( t \) utils to time \( t \) aggregate consumption units we need to multiply \( G_{i,t} \) by \( C_t^* D_t^* \).
Let $v_{i,t}^*$ denote this converted value; then it is given by

$$v_{i,t}^* = \max_{\{1_{i,t}, m_{i,t}\}} \sum_{\tau=1}^{\infty} (\beta \tau)^{s-1} \left( \prod_{h=1}^{\tau} 1_{i,h} \right) \left( C_t^* \right)^{-\gamma} \left( D_t^* Y(q_{i,t}) q_{i,t} - W_t^* (l_{i,p,t} + \chi) - C_t^* (D_t^* - 1) m_{i,t} \right)$$

subject to

$$y_{i,t} = m_{i,t} q_{i,t} C_t^* = z_{i,t} l_{i,p,t}.$$  \(\text{(D.60)}\)

**D.10 Proposition 9**

**Proof.** Recall that from Equation (3.18) the relationship between a firm’s production labor share and markup is given by:

$$\frac{W_t l_{i,p,t}}{p_{i,t} y_{i,t}} = \frac{\alpha}{\mu_{i,t}}. \quad (D.62)$$

Moreover, assuming $\delta = 1$, we can use the characterization of the firm’s optimal marketing strategy in Equation (3.23) to write their marketing labor share of an operating firm as

$$\frac{\phi^{-1} W_t l_{i,s,t}}{m_{i,t}} = (p_{i,t} - mc_{i,t}) q_{i,t} C_t \iff \frac{W_t l_{i,s,t}}{p_{i,t} y_{i,t}} = \phi(1 - \mu_{i,t}^{-1}). \quad (D.63)$$

Combining these two equations we get that

$$W_t l_{i,s,t} = \phi p_{i,t} y_{i,t} - \phi^{-1} W_t l_{i,p,t}. \quad (D.64)$$

Finally, notice that

$$SGA_{i,t} \equiv W_t \chi + W_t l_{i,s,t} = \underbrace{W_t \chi}_{=W_t \chi} + \underbrace{\phi Sales_{i,t}}_{=p_{i,t} y_{i,t}} - \frac{\phi}{\alpha} \underbrace{COGS_{i,t}}_{=W_t l_{i,p,t}}. \quad (D.65)$$

**D.11 Proposition 10**

**Proof.** This result can be derived from combining Equations (D.62) and (D.63):

$$\frac{W_t (l_{i,p,t} + l_{i,s,t})}{p_{i,t} y_{i,t}} = \alpha \mu_{i,t}^{-1} + \phi(1 - \mu_{i,t}^{-1}). \quad (D.66)$$

Notice that this is strictly decreasing in $\mu_{i,t}$ if and only if $\alpha > \phi$. Hence, the firm’s revenue productivity of labor, the inverse of the equation above, is increasing in $\mu_{i,t}$ if and only if $\alpha > \phi.$
E Computational Appendix

In this section, we present the details of the computation algorithm that solves and calibrates the model. We first describe the recursive representation of the firm’s problem. Then, we describe the law of motion of firms and characterize the stationary distribution. Next, we describe the algorithm that solves the model and the algorithm used in the calibration.

E.1 Solution Method

Firm’s Recursive Problem In period \( t \), a firm that decided to operate with a customer base of \( m_{t-1} \) and productivity \( z \) solves the following dynamic programming problem (which corresponds to the sequential representation in Equation (3.15)):

\[
v_t(m_{t-1}, z) \equiv \max_{l_p, l_p'} \left\{ py - W_t l_p - W_t (l_s + \chi) + \beta v \frac{U_{c,t+1}}{U_{c,t}} \mathbb{E}[V_{t+1}(m, z')] \right\}
\]

\[
s.t. \quad q = \left[ 1 - \eta \ln \left( \frac{p}{D_t (1 - \sigma^{-1})} \right) \right]^{\frac{\eta}{1 - \eta}}
\]

\[
y = mqC_t = z l_p^a
\]

\[
m = (1 - \delta) m_{t-1} + \frac{l_p^\phi}{P_{m,t}},
\]

where \( V_t(m_{t-1}, z) \equiv \max[0, v_t(m_{t-1}, z)] \) denotes the endogenous exit choice.

Stationary Distribution Let \( \mathcal{N}_t : M \times Z \rightarrow [0, 1] \) denote the cdf of incumbent firms measured after the realization of idiosyncratic productivity shocks, but before exit decisions are made. The law of motion of the distribution of firms is given by:

\[
\mathcal{N}_t(m, z') = \int_{M \times Z} F(z'|z) \mathbf{1}_{[m^*_t (m_{t-1}, z) \leq m]} \mathbf{1}_{[v_t(m_{t-1}, z) \geq 0]} d\mathcal{N}_{t-1}(m_{t-1}, z)
\]

\[
+ \lambda \int_{M \times Z} F(z'|z) \mathbf{1}_{[0 \leq m^*_t (0, z) \leq m]} \mathbf{1}_{[v_t(0, z) \geq 0]} dF^e(\nu),
\]

where \( F(z'|z) \) is the Markov chain given by the AR(1) productivity process, \( F^e(\nu) \) is the productivity distribution of potential entrants and \( m^*(m_{t-1}, z) \) denotes the optimal policy for customer acquisition.

Solution Algorithm In steady state consumption is constant, so that \( U_{c,t+1} / U_{c,t} = 1 \). The algorithm for the numerical solution of the steady state of the model is as follows:

Step 0: Set up a grid for firm’s state \( S = M \times Z \). We choose 15 collocation points in each dimension. For \( Z \), we use the 0.0001 and 0.9999 percentiles of the ergodic distribution of the AR(1) productivity process as the grid bounds. For \( M \), the lower bound of the grid is 0, and the upper bound is chosen so that the largest customer base in the solution of any version of the model is smaller than the bound. Given these bounds, we construct power grids to concentrate grid points at lower values for \( m_{t-1} \) and \( z \).

Step 1: Guess values for \( C, \tilde{W} \equiv W/(CD) \) and \( P_m \).

Step 2: Solve firm’s problem given \((C, \tilde{W}, P_m)\) by scaling the value function by \( 1/(CD) \) (this reduces the number of aggregate variables we need to solve for by one). We solve this problem by using projection methods to approximate both the value function \( v_t(m_{t-1}, z) \) and its expected value \( \mathbb{E}[V_{t+1}(m, z')] \). We approximate these functions with the tensor...
product of a linear spline in the $z$ dimension and a cubic spline in the $m_{-1}$ dimension. We follow a two-step procedure to compute optimal policies. First, for a given candidate $m$, we compute $q$, $l_s$ and $l_p$ by solving the nonlinear FOC for $q$ and using the production function and the law of motion of matches. Second, to optimize the value function with respect to $m$, we use the golden search method. Having approximated these values and guessed a vector of spline’s coefficients, we combine an iteration procedure and a Newton solver to find the coefficient of the basis function. To compute the expectation in $\mathbb{E}[V_{t+1}(m, z')|z]$, we rely on the following approximation

$$
\mathbb{E}[V_t(m, z')|z] = \sum_{i=1}^{50} \omega_i V_t \left( m, \exp(\rho \ln z + \epsilon_i) \right).
$$

To construct the nodes $\epsilon_i$, we generate an equidistant grid of 50 points from 0.0001 to 0.9999 and invert the CDF of the $\mathcal{N}(0, \sigma^2_2)$ distribution. To construct the weights $\omega_i$, we discretize the normal distribution with a histogram centered around the nodes.

**Step 3:** To approximate the ergodic distribution of firms, we construct a finer grid with 100 and 500 points in the $m_{-1}$ and $z$ direction, respectively. Then, we solve the firm’s problem on the new grid using the approximation to the value functions from the previous step.

To find the ergodic distribution, we rely on the non-stochastic simulation approach by Young (2010). This method approximates the distribution of firms on a histogram based on the finer grid. Since both optimal policies and productivity shocks are allowed to vary continuously, we assign values of $m$ and $z$ that do not fall on points in the grid in the following way. Let $s \equiv (m_{-1}, z)$ denote a firm’s state. Then, the transition matrix for a firm’s customer base can be constructed as:

$$
Q_M(s, m'(s)) = \left[ 1_{m'(s) \in [m_{j-1}, m_j]} \frac{m'(s) - m_j}{m_j - m_{j-1}} + 1_{m'(s) \in [m_j, m_{j+1}]} \frac{m_{j+1} - y'(s)}{m_{j+1} - m_j} \right]
$$

for all states $s$ in the grid. That is, the transition matrix allocates firms in the histogram based on the proximity of the optimal policy to each point in the finer grid. The transition matrix for productivity shocks is approximated as $Q_Z = \sum_{i=1}^{200} \omega_i Q_{z,i}$, where $Q_{z,i}$ is similarly constructed as in Equation (E.2) for $z'(s) = \exp(\rho \ln z + \epsilon_i)$. The overall transition matrix is then given by $Q = Q_Z \otimes Q_M$. Finally, the distribution of firms is obtained by iterating until convergence the approximation to the law of motion

$$
\mathcal{N} = Q' \left( v 1_{v(s) \geq 0} \mathcal{N} + \lambda 1_{v(s) \geq 0} F^e \right),
$$

where $F^e$ is an approximation of the distribution of entrants on the finer grid.

**Step 4:** Compute aggregate variable $X$ from firms’ vectorized policies $x(s)$ as $X = (v 1_{v(s) \geq 0} \mathcal{N} + \lambda 1_{v(s) \geq 0} F^e)' x(s)$. Compute the residual vector

$$
1 = \int_0^N m_i di, \quad 1 = \int_0^N m_i Y(q_i) di, \quad \text{and} \quad 1 = \frac{W}{\xi C^T L^w}.
$$

If the distance is small, stop. Otherwise, update $(C, \hat{W}, P_m)$ with a Newton method and go to **Step 2**.
E.2 Estimation routine

We estimate the parameters of the model via the Simulated Method of Moments (SMM). More specifically, we choose a set of parameters $\mathcal{P}$ that minimizes the SMM objective function

$$
\left( \frac{m_m(\mathcal{P})}{m_d} - 1 \right)' W \left( \frac{m_m(\mathcal{P})}{m_d} - 1 \right),
$$

where $m_m$ and $m_d$ are a vector of model simulated moments and data moments, respectively, and $W$ is a diagonal matrix. To compute the model simulated moments we follow these steps:

**Step 1:** Given a vector of parameters $\mathcal{P}$, we find the steady state of the model. For this, we slightly modify the previous algorithm. Since in the estimation we normalize aggregate output $C = Y = 1$ and the normalized wage $\bar{W} = 1$ (see Step 1 of the solution algorithm) with the free parameters $(\lambda, \xi)$, we need to solve for only one aggregate variable, $P_m$.

**Step 2:** We simulate 100,000 firms for 150 periods and compute model moments using data from the last 25 periods. When matching moments based on the entire US economy, we use data from all simulated firms. When matching moments based on Compustat data, we impose a filter that mimics selection into Compustat based on firm age and size. On the age dimension, we restrict the simulated sample to those firms that are at least 7 years old, as in Ottonello and Winberry (2020). On the size dimension, we restrict the sample to firms with sales above 19% of the average sales in the simulated economy. This cutoff corresponds to the ratio of the 5th percentile of the sales distribution in Compustat (USD1.06 million) to the average firm sales in SUSB (USD5.7 million) in 2012.

To minimize the SMM objective function and have confidence of reaching the global minimum, we follow a two-step procedure in the spirit of Arnoud, Guvenen, and Kleineberg (2019). In the first step, we construct 500 quasi-random vectors of parameters $\mathcal{P}$ from a Halton sequence, which is a deterministic sequence designed to cover the parameter space evenly. After computing the SMM objective in those points, we choose the 30 parameters vectors with the lowest objective values. In the second step, we initiate a local Nelder-Mead optimizer from each of the 30 starting points and select the local minimum with the lowest objective value.
F Additional Model Analysis

F.1 Identification of Model Parameters

In this section, we formally guide the discussion of the identification of model parameters. Panel A of Figure F.1 shows the local elasticity of simulated moments (rows) with respect to parameters (columns), evaluated at the calibrated parameters. In general, the intuition behind the choice of targets is borne out in the model. For example, a higher exogenous exit rate $1 - \nu$ mechanically increases the average exit rate. Similarly, a higher super-elasticity of demand $\eta$ increases the co-movement between revenue labor productivity and sales. A higher elasticity of the matching function $\phi$ makes the positive relationship between a firm's SGA expenses and sales stronger and reduces the co-movement between labor productivity on sales, as predicted in the simple version of the model in Propositions 9 and 10. The persistence of productivity shocks $\rho_z$ affects multiple moments, but it affects most strongly the dispersion of the sales distribution. Finally, a smaller average productivity of entrants $\bar{z}_{ent}$ increases the relative size of old firms.

We complement this discussion by analyzing the sensitivity measure developed by Andrews, Gentzkow, and Shapiro (2017), which shows the sensitivity of model parameters with respect to targeted moments. To make the numbers more comparable, we convert this measure into elasticities and plot $\left( \frac{J'(P) W J(P)}{P} \right)$, where $J(P)$ is the Jacobian evaluated at calibrated parameters, $W$ is the weighting matrix and $m_m(P)$ are the model moments evaluated at calibrated parameters. Panel B of Figure F.1 shows that the overhead cost $\chi$ is quite sensitive to the average COGS-to-OPEX ratio in the data. Similarly, the elasticity of substitution $\sigma$ is sensitive to the average production markup, and the standard deviation of the productivity shock $\sigma_z$ is most influenced by the standard deviation of employment growth.

F.2 Additional Calibration Figures

Here we provide additional results about the goodness of fit of the calibrated model. Figure F.2 plots the relationship between relative revenue productivity of labor and relative sales in the data (SUSB) and the model (both the raw data and a linear fit). The model is able to match the positive association between these variables well. Figure F.3 shows the relationship between relative SGA expenses and relative sales in the data (Compustat) and the model. Although the “Compustat-equivalent” sample from the model does not generate all the dispersion in relative sales as in the data, the relationship with relative SGA expenses is well matched in the overlapping range of relative sales. Finally, Figure F.4 plots the average COGS-to-OPEX ratio as a function of a firm's age and size in the data (Compustat) and the model. Here, age is normalized as time since entry into Compustat (which in the model occurs after the 7th year). In the model, the composition of firms’ costs exhibits a strong size profile and a weak age profile, as in the data.

F.3 Additional Analysis of Model in Steady State

This section further describes how the model works in the steady-state. First, we describe firms’ optimal policies. Then, we show the average firm dynamics, taking selection into account.

Firms’ Optimal Policies Figure F.5 shows firms’ steady-state optimal policy functions for three productivity levels (the 25th, 50th, and 75th percentile of the marginal productivity distribution in steady-state). The y-axis on the right plots the marginal distribution of the relative customer base.

(b) Sensitivity of Parameters

Notes: Panel A shows the sensitivity of simulated moments to parameters by computing the local elasticity of moments with respect to parameters. Panel B shows the sensitivity of calibrated parameters to moments by constructing the sensitivity measure of Andrews, Gentzkow, and Shapiro (2017) and converting it into an elasticity. Both measures are evaluated at the calibrated parameters.
Figure E.2: Model Fit: Labor Productivity and Sales

Notes: This figure plots the relationship between relative revenue productivity of labor and relative sales. Panel A and B show the relationship obtained from the SUSB data and the model simulated data, respectively. Each figure includes the best linear fit of the data. The x-axis is in log scale.

Figure E.3: Model Fit: SGA and Sales

Notes: This figure plots the relationship between relative spending in SGA and relative sales. Panel A and B show the relationship obtained from the Compustat data and the model simulated data, respectively. The model data is obtained by simulating the model and restricting the sample to firms that are at least 7 years old and have sales above 19% of the average sales in the simulated economy (which corresponds to the ratio of the 5th percentile of the sales distribution in Compustat to the average sales in SUSB). Each figure includes the local linear kernel best fit of the data.

While optimal spending in $l_{i,s,t}$ decreases with the size of the customer base, production labor is increasing in a firm's customer base. Thus, when firms have a small customer base, they spend more resources to increase it. However, due to decreasing returns to customer accumulation, firms increase their customer base gradually over time. As firms grow, they spend less on customer acquisition and more on producing goods to satisfy the growing demand. This is reflected in a firm's cost structure—the average COGS-to-OPEX ratio is also increasing in $m_{-1}$. As total output increases due to a larger customer base, the marginal cost of production also increases since production is subject to decreasing returns. This raises the price charged by the
Figure F.4: Steady-State COGS/OPEX by Size and Age

Notes: This figure plots the average COGS-to-OPEX ratio as a function of a firm’s age and size. Panel A and B show the relationship obtained from the Compustat data and the model simulated data, respectively. The model data is obtained by simulating the model and restricting the sample to firms that are at least 7 years old and have sales above 19% of the average sales in the simulated economy (which corresponds to the ratio of the 5th percentile of the sales distribution in Compustat to the average sales in SUSB). Age is normalized as years since entry into Compustat, which in the model corresponds to year 7.

A higher productivity allows firms to charge lower prices and higher markups. Thus, profits per marginal customer are increasing in productivity, which incentivizes firms to accumulate customers more quickly by spending more on $l_{i,s,t}$.

Figure E.6 plots firms’ optimal exit policies and the stationary joint distribution of $(m-1, z)$. Panel A shows the threshold productivity $z^*(m-1)$ such that if $z < z^*(m-1)$, the firm optimally chooses to exit. The figure shows that $z^*(m-1) < 0$, that is, firms with larger customer bases are able to survive large productivity shocks without the need to exit the market. Although a lower productivity reduces markups and profits per customer, aggregate profits are increasing in a firm’s customer base. Panel B shows that there is a positive correlation between firms’ productivities and customer bases in the steady-state.
Figure F.5: Firms’ Optimal Policies

Notes: These figures plot firms’ policy functions in steady state. Each figure shows policies as a function of relative customer base for three levels of productivity: the 25th, 50th and 75th percentile of the stationary productivity distribution. The y-axis on the right plots the stationary marginal distribution of the relative customer base.

Figure F.6: Optimal Exit and Stationary Distribution

Notes: Panel A plots the exit threshold $z^* (m_{-1})$ such that if $z < z^* (m_{-1})$, the firm optimally chooses to exit. Panel B shows the contour plot of the stationary joint distribution of $(m_1, z)$, censored at the 99th percentile of each variable.
Average Firm Dynamics with Shocks  Figure F7 plots the average firm dynamics taking selection into account. To construct this figure, we simulate a cohort of firms that starts with a zero customer base and draws productivities from the distribution of entrants. As firms are subject to productivity shocks, some decide to exit over their lifetime. The figure plots the average of each variable across firms that survived up to a given age.

Firms start with lower productivity, which grows over time due to the calibrated lower productivity of entrants and endogenous exit. Conditional on a productivity level, firms frontload spending on customer acquisition, and the average customer base and marginal costs rise rapidly for young firms. This, in turn, increases prices and reduces average output per customer and markups. Over time, only the most productive firms survive, so the average marginal cost and price decline, and output per customer and markups increase.
Figure F7: Average Firm Dynamics

Notes: The figure plots the average firm dynamics, which are obtained by simulating a cohort of firms that start with $m_{-1} = 0$, draw $z$ from the distribution of entrants, and experience productivity shocks over their lifetime. Each figure plots the average of a variable as a function of firms’ age across firms that survived up to that age.
Notes: This figure shows a scatter plot between relative productivity $z_i/\bar{z}$ and relative customer bases $m_i/\bar{m}$, for both the equilibrium and the social planner's allocation. We present three plots by varying the value of $\phi$, while keeping the remaining parameters fixed at the values in the baseline calibration. Low $\phi$ corresponds to 0.25, baseline to 0.53, and high to 0.75.

Notes: This table shows the set of moments targeted in the calibration of the Homogeneous customers model with an exogenous and homogeneous customer base. Avg. COGS-to-OPEX ratio refers to the average of the ratio across firms. Avg. cost-weighted production markup corresponds to the COGS-weighted average markup from Edmond, Midrigan, and Xu (2018). These moments were computed using data from Compustat in 2012. Slope of labor prod. on sales corresponds to the OLS coefficient of the sales-weighted regression of relative revenue labor productivity on relative sales from Edmond, Midrigan, and Xu (2018), restricting the sample to firms with relative sales above one. This moment was computed using data from the SUSB in 2012. The average exit rate was obtained from the BDS in 2012. The standard deviation of annual employment growth for continuing establishments is obtained from Elsby and Michaels (2013). Growth rate of variable x is computed as in Davis and Haltiwanger (1992): \((x_i,t - x_i,t-1)/0.5(x_i,t + x_i,t-1)\). The last column shows the model counterparts of each moment, which was obtained by simulating a panel of firms and computing each moment with the simulated data. In the model, we account for selection into Compustat by restricting the simulated sample of firms to those that are at least 7 years old and have sales above 19% of the average sales in the simulated economy (which corresponds to the ratio of the 5th percentile of the sales distribution in Compustat to the average sales in SUSB).

Figure G.1: Homogeneous Customers Model Fit: Firm Size

Notes: This figure shows moments targeted in the calibration of the Homogeneous customers model with an exogenous and homogeneous customer base. Panel (a) shows the model fit of the distribution of relative sales. The distribution of relative sales is obtained from the SUSB in 2012. Panel (b) shows the model fit of average employment, relative to 1-year-old firms, by firm age. Average firm employment by age group was obtained from BDS in 2012. In the calibration exercise, we only target the relative size of firms older than 10 years.
Figure G.2: Distribution of Markups: Baseline vs Homogeneous Customers Model

Notes: The figure plots the distribution of production markups in the baseline and re-calibrated homogeneous customers models. The vertical dashed lines show the average cost-weighted production markup in each model.
